Referees and Editorial Board

The members of the Program Committee would like to express their thanks to all of the professionals who contributed their time and expertise to the paper referee and editorial review board activities. Each technical and management paper submitted to the conference was reviewed by at least two referees. The referees who assisted the Program Committee in the selection of papers for the conference were:

H. Pat Artis
Thomas Bell
Thomas Beretvas
Mel Boksenbaum
Ethan Bolker
James Bowerman
William Brady
Bobby Brady
James Brennan
Jack Brey
Peter Burghardt
Cliff Burrell
Jim Calaway

After the selection of the papers, the members of the editorial review board were each assigned several papers for a thorough review. During this process, the editors provided the authors detailed suggestions about how to improve the quality and readability of their papers. The members of the editorial review board were:

H. Pat Artis
John Boelens
Bobby Brady
James Cheeseman
Kem Clawson
Chuck Comstock
James Cook
Claris Cottingham
Dottie Cunningham
Bernie Domanski
William Fairchild
Sidney Finehirsh
Dennis Foster

PROJECTION ALGORITHMS FOR IBM DASD CACHE ANALYSIS TOOL

Jean Ju and Stan Caldwell
International Business Machines Corporation

ABSTRACT

DASD Cache Analysis Tool (DCAT) is an IBM internal tool which models and projects the performance of both cached and uncached I/O subsystems. The current version covers MVS/XA, MVS/SP, VM/SP, and VSE environments. For MVS/XA, DCAT supports up to four hosts. DCAT provides performance information based on workload parameters, configuration, and device characteristics. Workload parameters are input by the user, calculated from system monitor data, or derived from migration sources. This article discusses projection algorithms used in DCAT. Comparisons of model results with benchmark measurements are also presented.

1. INTRODUCTION

DASD Cache Analysis Tool (DCAT) is an IBM internal tool which provides the ability to model I/O subsystem performance and to project the performance impact of DASD and cache migrations. This paper will cover the I/O subsystem model concentrating on algorithms used for projection.

First, a brief introduction of the general background of DCAT will be given. Input to the DCAT model includes device models, workload parameters, and configuration. DCAT supports devices 3350, 3370, 3375, 3380, 3380D and 3380E attached to control unit 3880 model 3. DCAT also supports the 3380 family attached to cached control units, 3880 models 13 and 23. Workload parameters are defined by users, derived from system monitor data, or calculated as part of the projection process. The configuration information is required in calculating the impact of I/O subsystem resource contention. The configuration is defined by specifying which devices belong to which LCU (Logical Control Unit) and what channel paths are available to each LCU.

DCAT provides a calibration capability which accepts system monitor data as input, and produces workload parameters to be used for projections and "what if" analysis. Major workload parameters include the activity rates, seek times, search times, and transfer sizes by device. A report is provided which compares the modelled results for that workload with the associated monitor data. Currently, DCAT supports monitor data for MVS/XA(RMF), MVS/SP(RMF), VM(MAP) and VSE(PT). The derived workload parameters can be used as a base for analysis using the projection options.

The user is typically interested in the performance impact given one or more of the following scenarios:

- an increase in the throughput requirement
- migration to a cached control unit
- migration to a new device type
- combination of multiple volumes onto a single device
- the addition of new devices to an existing string or control unit
- an increase in cache size
- migration from MVS/SP to MVS/XA

The projection option allows analysis of I/O growth projection and device migration. Sub-options allow the user to select various source volume combinations and mappings for the migration. Growth projections can be evaluated overall or for a subset of volumes based on user defined groupings called application groups in DCAT. The cache projection option focuses on cache migrations. The needed cache parameters can be input by the user or selected from typical workloads. This option also provides the ability to do sensitivity analysis on hit ratio or cache size.

This article will provide readers with a general understanding of DCAT so that they can discuss DCAT analysis provided by their IBM system engineers or adopt a DCAT approach for their own use.

2. SUBSYSTEM MODEL

Here we present an analytic model for predicting I/O subsystem performance. The model focuses on a simple form of channel program, such as this BDAM (Basic Direct Access Method) chain of CKD (Count Key Data) channel commands:

Seek
Set File Mask
Set Sector
Search ID Equal
Read

An equivalent ECKD (Extended Count Key Data) version has channel commands: Define Extent, Locate Record, and Read Data. To avoid unnecessary complexity, we will illustrate the model for a subsystem containing one string of 3380D attached to a 3880 model 3 control unit in an MVS/XA environment.

The model is based on queueing theory (Ref. 2). The channel program is treated as a request and the Unit Control Block (UCB) is viewed as a server. If an arriving request finds the UCB busy, then it will be placed on the UCB queue. The time it waits here for the UCB is reported by RMF (Resource Measurement Facility) as IOSQ (IOS Queue) time. After a channel program gets the UCB, it tries to access the device. If any component of the path to the device is busy, or if the device itself is busy, there is additional delay which is reported by RMF as PEND time. UCB service time is the sum of the physical device service time and PEND time. The physical device service time is broken into connect and disconnect time components, and reported by RMF as CONN time and DISC time respectively. UCB utilization is the product of the activity rate and UCB service time. Further breakdown of physical service time will be necessary for characterizing device and workload parameters. The components of physical device service time dealt with in the model are:

Seek: Time spent moving the access mechanism to the proper cylinder and track.
Latency: Time from end of seek until reconnect target sector.
RPS Delay: Lost revolutions due to failure in reconnecting.
Overhead: Portion of control unit overhead for the above BDAM channel program which is not overlapped with other service time components.
Transfer: Data transfer time for read/write commands.

Search: Time for repeated comparisons of record ID's or keys. In DCAT, the search time includes the pure search time as well as additional connect time spent handling more complicated channel programs.

Following is the list of terms for model variables which will be used in discussing DCAT's algorithms:

CONN: connect time
DISC: disconnect time
IOSQ: IOS queuing delay
LAT: latency
OVHD: non-overlapped control unit overhead
PEND: pend time
RESP: response time
RPSD: RPS (Rotational Position Sensing) miss delay
SEEK: seek time
SRCH: search time
STPDV: physical device service time
STUCB: UCB service time
XFER: data transfer time

The model can be summarized by the following formulas:

```
CONN  = OVHD  + SRCH + XFER
DISC  = SEEK  + LAT  + RPSD
STPDV = CONN  + DISC
STUCB = STPDV + PEND
RESP  = STUCB + IOSQ
```

The seek, transfer, and search times are functions of device characteristics and workload patterns. Half of the device rotation time represents the average latency. The overhead value is based on control unit measurements for the simple BDAM channel program. RPS miss delay and Pend time are calculated as functions of path utilization. RPS miss delay will be discussed in more detail in the next sub-section. It should be noted that for I/O operations on cached devices, read hits are satisfied directly out of the cache and have no disconnect time.

Pend time is relatively small for the single host case. It only involves delays associated with path busy at I/O initiation and is a function of the connect time and utilizations of storage directors and channels. For multiple host cases, when a device is shared, there can be a large Pend time due to the device being busy with another host. Benchmarks have shown that in many cases one host continues to monopolize a device until its queue of outstanding requests has been emptied. DCAT models this device level delay as a function of the device and UCB service times and utilizations. The model calculates IOSQ time by applying an M/G/1 queueing formula (Ref. 2) to the UCB service time and the UCB utilization. We would now like to give special attention to estimation of RPS miss delay.

2.1 RPS MISS DELAY

In Figure 1, two channel paths from the same MVS/XA host are connected with two storage directors in a 3880 control unit model 3. Sixteen 3380D devices can reconnect through either of two storage director-channel paths. Consider the case that device k is attempting to reconnect through storage director j and back to channel i. If only one LCU is connected to the pair of channels, the only opportunity for an RPS miss is when both storage directors are busy with other devices. There is no additional contention introduced by channels since a free storage director guarantees a free channel.

The RPS miss probability is calculated for each device. Let PSDM(j,k) be the conditional probability of an RPS miss in getting storage director j given that device k is not connected to storage director j. Then,

$$PSDM(j,k) = (USDj - USDjDVk) / (1 - USDjDVk)$$

where USDj = utilization of the jth storage director,
USDjDVk = utilization of storage director j by device k.

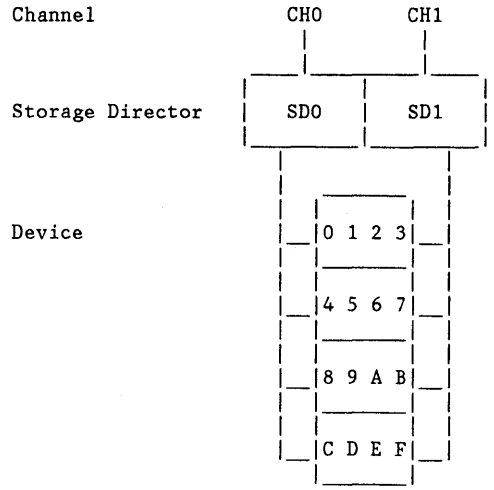

Figure 1. Subsystem Configuration for 3380D's Attached to 3880

The numerator represents the utilization of a path associated with other devices on this LCU and the denominator conditions upon this particular device not being currently connected to the storage director. Balanced loads are assumed for the two storage directors. The M/M/2 queueing formula (Ref. 2) is used to reflect MVS/XA's dynamic reconnect capability, which allows either of the two paths to be used in getting back to the host. Let PM be the conditional miss probability of an average reconnect attempt and U be total "conditional utilization" to two servers, then

$$PM = M/M/2 \text{ queuing of } PSDM$$
$$= 1 - ((1 + U) / (1 + U + (U \times U) / (2 - U)))$$

where U = 2 x PSDM

This equation will be applied to each device. In multiple host environments, the storage director utilization is the total utilization from all hosts since interference with reconnection might come from any source.

Configurations which involve two or more LCU's sharing two channels require that channel contention be considered. Assume that device k belongs to LCU m. Let PCHM(i,m) be the conditional probability of an RPS miss in getting channel i given that a storage director in LCU m is available, then

$$PCHM(i,m) = (UCHi - UCHiLCUm) / (1 - UCHiLCUm)$$

where UCHi = utilization of the ith channel,
and UCHiLCUm = utilization of channel i by LCU m.

Apply the M/M/2 queueing formula to PSDM and PCHM and compute the following probabilities for n = 0, 1, and 2.

PSDB(n) = conditional probability of n storage directors (in this LCU) busy with other devices, given that device k is not connected
PCHB(n) = conditional probability of n channels busy with other LCU's, given that a storage director is available in LCU m.

The probability of a miss for a storage director-channel pair is a function of PSDB's and PCHB's. A matrix of coefficients is applied to the product of PSDB and PCHB, since the availabilities of storage directors and channels

are not independent. The probability of miss can be expressed as

```
      PM   = Sum of (PSDB(i) x PCHB(j) x COEF(i,j))
             for 0 =< i,j =< 2,
where COEF =  0  0  1
              0 .5  1
              1  1  1
```

For multiple host cases, these formulas will use total device and total storage director utilizations and the individual channel utilizations from each host. Remember that PM is the miss probability for an individual reconnect attempt; there can be more than one miss for a single disconnect. The expected number of misses per SIO will be PM / (1 - PM). This can be viewed as the rate of failures per success. The model assumes there is one successful reconnect per SIO; so it is the miss rate per SIO. Finally, the RPS miss delay is

RPSD = rotation time x PM / (1 - PM).

2.2 RMF CALIBRATION

The subsystem model described above assumes components of the response time are available or can be calculated according to DCAT's algorithms. If a user starts with RMF data and runs through the DCAT calibration option, he will end up with a file containing workload parameters corresponding to his RMF data. Those workload parameters can be used to derive components of the response time. DCAT then compares the modelled response and service times with RMF data and reports the calibration ratios.

Let us take a closer look at RMF data for the MVS/XA environment. RMF reports physical device service time in two parts: disconnect time (DISC) and connect time (CONN). The formulas for disconnect and connect times which will be used to describe the calibration process are repeated below:

```
STPDV = DISC + CONN
DISC  = SEEK + LAT  + RPSD
CONN  = OVHD + SRCH + XFER
```

For uncached control units, the process of calibration can be explained simply. Given RMF data and configuration, the workload parameters SEEK, SRCH, and XFER can be estimated as follows:

DISC: First calculate RPSD based on configuration and path utilizations. Derive SEEK as follows:
SEEK = DISC - LAT - RPSD.

CONN: Split (CONN - OVHD) into SRCH and XFER based on historical ratios of SRCH and XFER.

When a configuration includes a cached control unit, multiple channel program types are considered when determining components for disconnect and connect times. For example, a read channel program which finds its data in cache will not require device access and will contribute zero time to the average disconnect reported by RMF. Also the SRCH time for a search in cache will be less than the SRCH time for a search requiring device rotation. Therefore, the rules are similar to the uncached case given above but are lengthier because that multiple channel program types are used and each channel program type may contribute different amounts to disconnect and connect times. The implementation of the above process involves iteration and requires input of cache statistics such as the ratio of reads to writes and the fraction of reads which are satisfied in the cache.

For MVS/SP, VM, and VSE environments, the monitor data does not break down the device service time into disconnect and connect components. DCAT uses the channel service time, which can be derived from the channel utilization, as an estimate of connect time for each device. The disconnect time is obtained by subtracting the connect time from device service time, and then the procedure discussed above is applied.

Once the workload parameters have been generated, the user can use these parameters in running the regular model to do 'what if' analysis. There are some limitations on this calibration scheme. It focuses on a simple form of channel program as described in the beginning of this section. Some applications generate channel programs which do not match the simple pattern; for example, there may be no Set Sector or Locate command. Devices which include a significant amount of "unusual" activity will not calibrate. In general, the disconnect and connect times have lower bounds: a half of the rotation time and the channel overhead, respectively. Any volume used primarily by applications which generate smaller disconnect or connect time than these limits will have trouble calibrating. Typically the number of volumes and fraction of I/O which exhibit this behavior is small and the overall subsystem calibration remains good.

Experience shows that in MVS/XA environments, the model calibrates to within 1% of the RMF data. In non-MVS/XA environments, since connect times are not provided for each device and must be estimated, calibration within 5% to 10% of the measured data is typical.

3. MIGRATION AND SEEK PROJECTION ALGORITHM

We will cover general algorithms for growth and migration first. Then we move on to the seek projection algorithm, which is a major issue for device migration.

In the growth scenario, those variables which change are prefaced by 'G'; other variables remain the same. The growth that is being modelled is an increase in I/O rate for all or a subset of the volumes. The migration scenario assumes that a set of volumes are being moved from their current devices to some new device type. This move may involve folding several volumes from small devices onto a single larger capacity device. In this case, variables prefaced by 'W' indicate that the variable will be a simple weighted average of the original volume variables. A prefix of 'M' indicates that this variable will be affected in other ways by the migration.

3.1 WORKLOAD GROWTH

For growth projection, we have disconnect, connect, and pend times as below:

GDISC: RPS miss delay will be grown with the activity rate and utilizations.
GDISC = SEEK + LAT + GRPSD

GCONN: The average connect time for each SIO remains the same.
GCONN = CONN

GPEND: Pend time will be grown with the activity rate and utilizations.

After the variables are changed as described, DCAT will output the response time, service time, and utilizations based on the increased I/O rate. Results are provided at an overall summary level by volume and by application group since an increase in I/O rate for one application can have a negative effect on response time for another.

3.2 DEVICE MIGRATION

Now consider a group of source volumes that are to be migrated to a new group of target devices. For each target device, disconnect, connect, and pend times can be determined by the following rules:

MDISC: Calculate MSEEK according to the seek projection algorithm. Calculate MRPSD according to new configuration, utilizations, and activity rates for target devices. Use half of the rotation time of the target device as the new latency.
MDISC = MSEEK + MLAT + MRPSD

MCONN: Assign the weighted averages of source search times and source transfer times as the search and transfer times of the target device. The overhead may change if the migration involves a new control unit or micro code load.
MCONN = MOVHD + WSRCH + WXFER

MPEND: Pend time is a function of new configuration, service time, utilizations, and activity rates.

3.3 SEEK PROJECTION

The average seek time of the target device will be determined by the pattern of seeks on source volumes and additional arm stealing among volumes introduced by the migration. Arm stealing occurs when two or more datasets are busy in a small time window. We will be able to estimate the target arm stealing rate if we can establish a dataset busy distribution for the target device. Assume for the moment that probabilities of zero, one, and two or more datasets busy are known for each source volume in a small window. The target device has no dataset busy if and only if all the source volumes have no datasets busy. The target device has one dataset busy if and only if exactly one source volume has one dataset busy. The hidden assumption here is that the activities of the source volumes are independent. We can express the above algorithm mathematically by means of the following notation:

A0(i): Probability of no dataset busy in source device i

A1(i): Probability of one dataset busy in source device i

A2(i): Probability of more than one dataset busy in source device i

B0: Probability of no dataset busy in the target device

B1: Probability of one dataset busy in the target device

B2: Probability of more than one dataset busy in the target device

Then the relationship among Ai's and Bi's for n-to-1 mapping follows:

$$
\begin{aligned}
B0 &= A0(1) \times A0(2) \times A0(3) \times .. \times A0(n-1) \times A0(n) \\
B1 &= A1(1) \times A0(2) \times A0(3) \times .. \times A0(n-1) \times A0(n) \\
&\quad + A0(1) \times A1(2) \times A0(3) \times .. \times A0(n-1) \times A0(n) \\
&\quad + A0(1) \times A0(2) \times A1(3) \times .. \times A0(n-1) \times A0(n) \\
&\quad + ... \\
&\quad + A0(1) \times A0(2) \times A0(3) \times .. \times A1(n-1) \times A0(n) \\
&\quad + A0(1) \times A0(2) \times A0(3) \times .. \times A0(n-1) \times A1(n) \\
B2 &\text{ satisfies } B0 + B1 + B2 = 1
\end{aligned} \qquad (1)
$$

The following regression formulas which are used to get probabilities of dataset busy and average seek times are extensions of techniques described in Ref. 3. The trace data used there were collected during peak-load time intervals at two large installations.

Let

ACTR: Activity rate

K1,K2,K3: Coefficients

Tr: Nominal seek time

Ts: Average seek time within a single dataset

THETA: Arm-stealing rate

Then

$$
\begin{aligned}
SEEK &= (1 - THETA) \times Ts + THETA \times Tr \\
THETA &= (K1 + K2 \times A2) / ACTR \\
ACTR/K3 &= A1 + A2 \\
1 &= A0 + A1 + A2
\end{aligned} \qquad (2)
$$

where Ts/Tr = 0.1, K1 = 0.1, K2 = 30, and K3 = 30

The first formula means the average seek time can be estimated by the the nominal seek time when arm stealing occurs and by the average seek time within a single dataset when there is no arm stealing. By applying these regression formulas, DCAT can derive probabilities A0(i), A1(i), and A2(i) for each source volume i. Then it uses equation set (1) to gain dataset busy probabilities B0, B1, and B2 for the target device. Finally, it applies equation set (2) again to derive the average seek time for the target device. Some modifications are needed to assure that all probabilities stay between zero and one.

$$0 =< A0, A1, A2, (A1+A2), \text{ and } THETA =< 1.$$

Also, modifications are applied to account for the "short-stroke" effect when there is one dominant source volume. Further discussion on the short stroke effect can be found in Ref. 1.

2-to-1 mapping:
Modified Target Seek = 0.90 x Target Seek
3-to-1 mapping:
Modified Target Seek = 0.84 x Target Seek
4-to-1 mapping:
Modified Target Seek = 0.81 x Target Seek

This seek projection algorithm has been validated using simulation runs. The simulation looks at trace data to determine the pattern of seeks and seek distance for each I/O. The seek time associated with these seek distances is based on actual device measured seek curves, and an average time for each volume is generated. To simulate a migration to 3380E from 3380 (2-to-1), the assumption is made that data from the first 3380 occupies cylinders 0--884 and data from the second is on cylinders 885--1769. The traces for the two volumes are merged and a new seek sequence is generated. The average time for this new migrated sequence can then be compared with what is predicted by DCAT's algorithm. In general, the simulation is somewhat pessimistic since the possible data compression of empty space on the volumes is not being accounted for. Also, the new larger volume would have only one VTOC (Volume Table Of Contents) and hence would not have the arm stealing between VTOC's which is simulated.

Simulations were run with customer I/O trace data and set up to cover various n-to-1 mappings and two different foldings -- slide and random. It is convenient to define slide folding by an example. Say there are 12 devices being numbered according to the order of their activity rates. For 2-to-1 mapping, slide folding will put device pairs (1,7), (2,8),..., (6,12) as target devices. For 3-to-1 mapping, it has sets (1,5,9), (2,6,10), (3,7,11), and (4,8,12). The complete mappings between source and target devices are illustrated as below:

Slide Folding:	source devices ordered by activity rates						
2-to-1 mapping	---------->	1	2	3	4	5	6
	---------->	7	8	9	10	11	12
		:	:	:	:	:	:
	Target Device	1	2	3	4	5	6
		:	:	:	:		
3-to-1 mapping	---------->	1	2	3	4		
	---------->	5	6	7	8		
	---------->	9	10	11	12		

Slide folding is used in DCAT when the default migration option is selected. It will provide a reproducible and relatively conservative distribution of activity among target devices. The optimal folding for the 2-to-1 mapping for the above example will put device pairs (1,12), (2,11), ..., (6,7) as target devices. DCAT does not pick

this optimal folding as the default since the folding that is optimal overall is unlikely to be observed during any one particular interval, and was therefore thought to be too optimistic. Random folding corresponds to a user assigning the migration mapping with no information or knowledge of device activity. Since users can normally identify their busier volumes, this random approach was felt to be too pessimistic. However, the seek projection algorithm was checked for random folding to ensure the coverage of this extreme case.

Comparisons of analytic seek projections versus simulation runs are plotted in Figures 2 to 6. The first three figures show comparisons for 2-to-1, 3-to-1, and 4-to-1 mappings for the slide folding. The next two figures show all mappings for slide folding and for random folding. The scale is normalized by the nominal seek of the target device. The points on the line from (0,0) to (1,1) correspond to the analytic and simulation results being identical. All five plots demonstrate reasonably good matches between the analytic model and the simulation.

We have studied other approaches for the seek projection algorithm which use the average of all possible combinations of 2-to-1 mappings. Compared to those approaches, this algorithm is independent of the order of source devices and saves computing time. In addition to the simulation validation, measurements have been used to do an overall validation of the device migration scenario, and are presented in section 5. We believe the seek projection algorithm presented in this section to be a reasonably fast and accurate approach for both slide and random foldings.

4. CACHE PROJECTION AND ITS ALGORITHMS

4.1 UNCACHED TO CACHED CONTROL UNITS

Up to this point we have centered the discussion on how DCAT models the uncached devices. The DCAT model for cached devices is similar but where the uncached activity is reduced to one simple BDAM channel program, the cached activity is reduced to multiple channel program types. The four most important channel program types are: read hit, read miss, write hit, and write miss. For the 3880 model 23, all but the read hit channel program type in-

clude access to the physical device, which means that the service time includes seek, latency, and RPS miss delay.

For modeling a cached control unit, determining the allocation of a device's throughput among the various channel program types is extremely important. For example, a Start I/O which only reads 4K data bytes and finds the data in cache storage can have a response time in the 3 to 4 millisecond range since no device activity is involved. Also contributing to the low service time for read hits is a faster search in cache versus a comparable search time on a physical device. The same SIO occurring as a read miss would be similar to an uncached SIO and might take 25 to 30 milliseconds. Therefore, two additional important workload parameters for each cached device are read-to-write ratio (RWRATIO) and read hit ratio (READHIT).

The cache projection portion of DCAT allows a user to project from uncached to cached control units, project from one average hit ratio to another, and project from one cache size to another.

Projecting from uncached to cached configurations requires that DCAT query the user for the needed cache parameters. The user has the option of deriving the cache parameters for the system being modeled or letting DCAT default the parameters. The most accurate method is for the user to derive the cache parameters from data collected on the system being being modeled. The Cache Analysis Aid (CAA) tool is available for the user which analyze trace data to determine the read-to-write ratios and the read hit ratios for different cache sizes. For those studies not requiring this level of accuracy, DCAT can provide "canned" cache parameters based on measurements previously done at installations with similar workloads.

4.2 HIT RATIO PROJECTION

Projecting from one average hit ratio to another is done by giving the user the current average hit ratio for a control unit and allowing the specification of a different average. DCAT takes the new average hit ratio and adjusts the individual device hit ratios before running the model.

When developing the algorithm to determine new device hit ratios, many things had to be considered. For example, if the target average hit ratio is larger than the original average hit ratio, then it was felt that all the device hit ratios would probably increase. Also it was felt that a device with a high hit ratio would probably not increase as much as a device with a low hit ratio. The above two conditions had to hold in reverse when the target average hit ratio is less than the original average hit ratio.

Another thing to consider was, if the target average is 0, 1 or equal to the original average, then the individual device hit ratios need to be 0, 1, or equal to the original device hit ratios respectively. In addition, all hit ratios are bounded by 0 and 1. Part of the original challenge was to find an algorithm which was reversible such that one could project to a target average hit ratio and reverse the process arriving at identical device hit ratios as at the starting point. The algorithm presented does have the property of reversibility until any device hit ratio starts at a boundary or is projected to a boundary. In order to provide the property of reversibility, the original device hit ratios would have to be kept. The property of reversibility was not important enough to justify the additional storage required.

The algorithm is as follows:

HR(i) - the read hit ratio of device i, which is the current setting

AHR - average read hit ratio of all devices on a control unit (average of HR(i) weighted by read I/O rate)

PHR(i) - the projected read hit ratio of device i, computed below

APHR - average projected hit ratio (target provided by user)

If APHR >= AHR

$$\text{then} \quad PHR(i) = HR(i) + \frac{APHR - AHR}{1 - AHR}(1 - HR(i))$$

If APHR < AHR

$$\text{then} \quad PHR(i) = HR(i) - \frac{AHR - APHR}{AHR} HR(i)$$

Since the above algorithm increases high device hit ratios less than low device hit ratios when the average increases, the overall effect is to produce a set of hit ratios that approach the average. The function is simple and has been validated using a trace driven simulator (CAA) which provides hit ratios for different cache sizes.

4.3 CACHE SIZE PROJECTION

Projecting from one cache size to another is accomplished by giving the user the current cache size and average hit ratio for a control unit and allowing the specification of a different cache size. DCAT uses old cache size, new cache size, and old average hit ratio to first determine a new average hit ratio. The new average hit ratio is then used with the old hit ratios for each device to generate new hit ratios by the method described previously.

To determine a new average hit ratio for the new cache size, additional data is used by DCAT. This data is a table showing read hit ratio vs. cache size per MB of back store for each workload. This table has been generated from analysis of numerous measurements at computer installations using cached DASD.

The algorithm for mapping from one cache size to another is as follows:

1. Using the old average hit ratio and the function of read hit ratio vs. cache size per back store size, determine what the cache size per back store is for the old average hit ratio. Note that this value may or may not be identical to the actual cache size per back store.
2. Multiply the cache size per back store determined in step 1 by the ratio of the new cache size divided by the old cache size. Thus, if the new cache size is 48 MB and the old cache size was 32 MB, we would multiply the step 1 cache size per back store by 1.5.
3. Using the resulting cache size per back store from step 2 and the function of read hit ratio vs. cache size per back store size again, determine the new average read hit ratio.
4. Finally, generate the DASD hit ratios by the method described previously for projecting from one average hit ratio to another.

Clearly this method needs the function of average hit ratio vs. cache size per back store size to hold for all users with the same workload. Different workload types indeed have different characteristics for this average hit ratio function. For example, a workload such as TSO that is extremely favorable for caching quickly generates a high hit ratio at low values for cache size per back store size, then slowly builds from there. With the technique described above, and if a low old average hit

ratio is given for TSO, then almost any increase of cache size per back store size will show a dramatic increase in hit ratio. On the other hand, if the old average hit ratio is already high (.90 or larger), then it takes sizeable cache increases to get a significant increase in the average hit ratio.

The projection based on cache size change can be validated easily using the CAA tool that provides hit ratios for different cache sizes. The projected hit ratios are checked against the actual hit ratios. The method described above consistently provides hit ratios that are within an acceptable delta from the actual hit ratios.

5. VALIDATION

Validation of DCAT can be broken into two questions. The first question is: How accurate a set of workload parameters does DCAT generate during its calibration step? The second question is: How accurately does DCAT project to different environments or different workloads?

The calibration step consistently generates a set of workload parameters that provide model results for response and service times that are within 1% of the monitor values in MVS/XA environments. This may be comforting to the DCAT user when reported at the end of the calibration step; but in reality, generating a single set of workload parameters which matches the input values is easy. There are a multitude of sets of workload parameters which would satisfy the monitor data.

For example, when deciding how to divide the connect time between search and data transfer, we could assume no search with all data transfer, or all search with no data transfer, or somewhere in between. Unfortunately there is no monitor data available to provide hints. The split between search and data transfer is important when projecting to a cached control unit since the search time will be reduced but the data transfer time will not. DCAT divides the search and data transfer based on ratios measured from installations with similar workloads.

The result of all this is that the answer to the first validation question on accuracy of the calibration step is answered by looking at how well we are able to use this workload to project to different environments and workloads.

Many "what if" questions can be answered with the DCAT projection option as mentioned in Section 1. Each of the "what if" questions can be validated using various configuration and workload assumptions. We would like to present the results of three sets of validation runs here. The methodology involved obtaining measurements of base and target configurations and workloads which contained a device migration or I/O rate growth scenario. The base was entered in DCAT and a calibration step performed to generate a set of workload parameters. DCAT was then used to predict the performance of the target configuration or I/O rate. The model projected response times and service times were then compared to the measured data for the actual target benchmark. The workloads used were TSO and IMS benchmarks run in a laboratory environment. The configuration included one control unit, either 3880 model 3 or 3880 model 23 with 16MB to 32MB cache storage. The control unit had dedicated channel paths. The devices measured were: sixteen 3380 standard actuators, sixteen 3380D's, or eight 3380E's. Some runs involved accesses from multiple hosts. The first set of comparisons demonstrates how well DCAT projects growth in I/O rate. Table 1 lists eleven runs of workload growth with growth rates from 22% to 102%. The naming convention for run ID's are as follows: the first three characters, TSO or IMS, indicate the workload; the fourth, N or C, states 3880 model 3 or model 23 (cached); the last one is just a hexadecimal run number. The ratios of projected service times over measured service times are between 0.96 to 1.03. The similar ratios for response times are between 0.94 to 1.08.

TABLE 1. Validations for Workload Growth

RUN ID	BASE			PROJECTED			MEASURED		PROJ/MEAS	
	IO	ST	RT	IO	ST	RT	ST	RT	ST	RT
Single Host										
TSON1	102	21.0	24.6	142	24.9	32.8	24.6	32.6	1.01	1.01
TSON2	102	22.6	32.6	142	27.1	59.7	26.8	62.3	1.00	0.96
IMSN3	78	18.1	21.8	110	19.2	26.6	19.9	26.1	0.97	1.02
IMSN4	114	19.9	26.1	151	21.8	38.0	22.6	35.3	0.96	1.08
Multiple Host										
TSON5	135	18.3	25.9	165	20.0	33.9	19.7	33.7	1.02	1.01
TSON6	70	17.1	21.2	92	17.6	23.7	17.4	23.8	1.01	0.99
TSON7	92	17.4	23.8	125	18.4	30.1	18.1	30.6	1.02	0.98
TSON8	70	17.1	21.2	125	18.6	29.4	18.1	30.6	1.03	0.96
TSON9	55	18.3	20.8	111	20.9	29.0	21.1	28.2	0.99	1.03
TSONA	76	18.9	22.4	106	20.5	26.9	20.9	28.5	0.98	0.94
TSOCB	53	11.5	13.3	104	12.9	16.3	12.9	16.6	1.00	0.98

The second set of comparisons demonstrates how well DCAT projects performance when device migration is involved. There are seven pairs of runs for single host environments. Each pair consists of a 1-to-1 migration and a 2-to-1 migration with the same base. The 1-to-1 run represents the migration from sixteen standard 3380's to sixteen 3380D's. The 2-to-1 run has eight 3380E's as targets. These 14 runs are listed in Table 2. The naming convention is similar to that used in Table 1. The ratios of projection over measurement are 0.97 to 1.06 for service times and 0.94 to 1.16 for response times.

The third set of comparisons demonstrates how well DCAT projects when a control unit is upgraded with cache storage. Essentially, devices are moved from a uncached 3880 model 3 to a cached 3880 model 23. There are 12 cases listed in Table 3. The fifth character "C" of the run ID indicates that this is a cache projection. The ratios for service times are between 0.93 to 1.11, and the ratios for response times are between 0.88 to 1.12. Prior to any validation work, we have generally agreed that 20% is the acceptable tolerance for response time and physical service time differences.

6. SUMMARY

The normal use of DCAT involves collecting monitor data and running it through the calibration option. The resulting workload is then used to project to different environments and workloads.

The crucial algorithms for the subsystem model and projection -- namely, the RPS miss delay calculation, the seek time projection, and the cache migration -- have been in a process of change and evolution as we obtain more measurement data for validation. The algorithms were developed and validated with the help of special purpose simulation models as well as the measurements described. The validation efforts done to date show that the projection algorithms are consistently providing results within an acceptable range.

DCAT has been getting worldwide usage within IBM since 1985, and the user response has been favorable. In the US alone, the monthly averages for DCAT indicate 300-400 users accounting for 1500-2000 sessions. DCAT has helped IBM system engineers working with customers to suggest cost-effective configurations which meet their requirements.

ACKNOWLEDGEMENTS

DCAT has been successful only because of the expertise and efforts of many people. A few of them are: Linda Duyanovich for her pioneer work on DCAT and many helpful suggestions for DCAT and this paper; Gordon Nouhan, Annette Spaeth, and Ruth Cintron for their development efforts to mold the above ideas into useful products; Ed Nauss for his efforts in laying a good foundation for the subsystem model with his simulation; Marc Goldfeder whose ideas make up the cache modeling and the cache projection algorithms; and Bruce McNutt for his work on seek projections upon which DCAT's technique was built.

A MULTIPLE WORKLOAD APPROACH TO CACHE PLANNING

Bruce McNutt and James W. Murray
International Business Machines Corporation
San Jose, California

ABSTRACT

Cached controllers can provide a powerful and cost-effective tool for speeding up the I/O activity at an installation. This is true even if the cache is simply installed and turned on. Provided that a large enough amount of cache memory is provided, no particular planning is required to obtain good results.

Long-term planning can, however, enhance the cost-effectiveness of cache and can simplify the cost-justification process, by taking into account the value of high performance for specific applications. The purpose of this paper is to introduce a set of techniques which may be helpful in choosing a strategy for the use of cache which best meets the needs of a given installation, if a large number of possible options is being considered. This is done by breaking down the data to be cached into workload-related volume groups, or "pools". For example, an installation might be considering the purchase of either one, two, or three cached controllers, which would be used to cache some subset of the key system data, the TSO user data, and three data bases of various types. For each cache, a choice among several memory sizes must also be made. An approach to this problem is introduced in which the locality of reference is estimated separately for each individual pool which may share the use of a cached controller. Requirements for cache memory are also estimated for each pool. The proposed approach then allows these estimates to be applied to shared caches containing any combination of the original pools. This procedure makes possible the efficient examination of a large number of potential cached configurations.

1. INTRODUCTION

Cached controllers can provide a powerful and cost-effective tool for speeding up the I/O activity at an installation. This is true even if the cache is simply installed and turned on. Provided that a large enough amount of cache memory is provided, no particular planning is required to obtain good results. If there is a question as to the amount of memory which is required, then this can be resolved through the use of a cache simulation tool such as Cache Analysis Aid [1, 2].

Long-term planning can, however, enhance the cost-effectiveness of cache and can simplify the cost-justification process, by taking into account the value of high performance for specific applications. The purpose of this paper is to introduce a set of techniques which may be helpful in choosing a strategy for the use of cache which best meets the needs of a given installation, if a large number of possible options is being considered. This is done by breaking down the data to be cached into workload-related volume groups, or "pools".

As an example, imagine an MVS shop where we have put together the following list of volume groups ("pools") as caching candidates:

1. A select group of performance critical ("key") system volumes, containing master catalogs, heavily used program libraries, the IMS long and short message queues, the Hierarchical Storage Manager (HSM) and Resource Access Control Facility (RACF) control data sets, and other control and/or widely shared data.
2. A decision support system data base, used for interactive planning and analysis by upper level management.
3. Twenty TSO user volumes.
4. An inventory data base, used for tracking the status of warehouse items.
5. An accounts payable data base, used for batch billing and on-line inquiries.

Each of these candidate volume pools accounts for a different proportion of the total I/O activity. In addition, each has a certain service priority; the key system volumes must have the highest priority of good response, the priority of the decision support system comes second, and the remaining pools are all to be treated as equal. Finally, each of the candidate pools will benefit differently from the use of cache.

We are now confronted with the problem of selecting which subset of these candidate pools to place under a cache, how many caches to buy, how to mix the cached pools onto the available caches, and how much cache memory will be needed. For example, we might choose to place the key system volumes on cache 1 and the decision support system data base on cache 2; or to combine the decision support system with the inventory data base on cache 2 while cache 1 continues to handle the key system data; or to place both the key system volumes as well as the decision support system on cache 1, while cache 2 contains the TSO user volumes; and so on.

This paper shows that the time-honored approach of problem decomposition can be applied in addressing questions of the kind described above. Through the techniques developed below, individual data pools can be examined first, and the performance of collections of pools can be projected by building upon the pool-by-pool results.

The data used to drive the proposed approach is obtained by applying a cache simulation, such as that performed by the Cache Analysis Aid, to a Generalized Trace Facility (GTF) trace of I/O activity, including channel control words (CCW's). Cache simulations can be used to estimate the hit ratio and read/write ratio of the cache assuming that the backing store contains any specified group of volumes (e.g. any data pool), and assuming a range of cache memory sizes which might be selected [1 - 3]. These parameters are the key to determining the performance benefits which the cache is likely to achieve [1, 4 - 5]

In the multiple-workload approach, information obtained from cache simulations is used to describe the behavior of the cache individually for each pool. This paper introduces a set of techniques which allows the pool-by-pool simulation results to be combined to obtain a prediction of the overall performance of a cache which contains two or more pools. To estimate the impact on such a cache of adding a pool, removing a pool, or caching some other combination of pools, the same basic performance data for each pool can be re-used, as many times as needed, in different combinations.

The key making the above strategy of decomposition work is to view the hit ratios obtained from the simulation as being a function of the average time which a track spends in the cache. The construction of this view of the data is straightforward if the data provided from the simulation includes a broad range of hit ratios and corresponding cache sizes. The central result reported in this paper is that, once the hit ratio of each pool is expressed as a function of the average time in cache, it is possible to predict with very high accuracy the hit ratio on a cache containing mixed pools, as a function of either the average time in cache or of cache memory size.

These results mean that in the example MVS installation discussed above, a very broad range of possible configuration options can be explored by using the results of only five cache simulation runs (one for each pool). Once these five runs have been performed, planning can proceed by mixing and matching the five pools onto various numbers of caches. For a given cache containing a specific mixture of pools, the hit ratios and read/write ratios for each pool are estimated separately, as are the corresponding cache memory requirements. Since these data are available separately for each pool, the

actual benefits can be assessed easily for each pool depending on the relative priority of service for that pool. The total cache memory requirements for the cache as a whole are obtained simply by adding the requirements for each pool. The overall hit ratios and read/write ratios can also be obtained by aggregating the individual pool data.

The strongest results of this paper are a number of test cases, based on live installation data, where the above procedure for combining pool data was employed successfully to predict the performance of a mixed cache configuration. These results represent a variety of different computing environments, but may not necessarily be representative of all environments and configurations. For this reason, the paper starts off in Section 2 with an overview of the trace data, collected from twelve different installations and subdivided into five standard pools, which was used as a basis for the test cases. Section 3 then motivates the idea of expressing the hit ratio as a function of the average time in the cache, and explains why we should expect it to be possible to combine a function of this kind across pools. Section 3 also develops the specific procedure used to obtain this function from simulation results, and proposes the method which would be used to combine two or more such functions in order to evaluate the case of a mixed cache.

Section 4 tries out the idea of hit ratios expressed as a function of the average time in cache. For each standard pool (CICS data base, IMS data base, TSO user data, BATCH data, and KEY SYS data), and for each installation where a pool of this kind was traced, we present the hit ratio curve as a function of the average time in the cache. These curves provide an interesting comparison of the differences and similarities in the cache performance of a given type of data across a number of installations, and they yield some useful clues about the range of performance which may be achievable by using cache for specific types of installation data. Section 5 then tests the major premise of the paper. For a selected list of pool pairs (not all possible combinations!), predictions are developed of the hit ratio as a function of the average time in the cache. These predictions are tested against the result of a simulation based on merged traces of the activity from both pools. The results show that the predicted hit ratio is never off by more than 1.4 percentage points.

Figure 1. Overview of Trace Data

Figure 1 presents an overview of the data which we will be talking about in the rest of the paper. This data is an outgrowth of an ongoing project to collect information about how DASD are used in live installation environments.

As Figure 1 shows, trace data was collected from twelve installations. At each installation, data was collected over a period of at least 15 minutes (for complexes A and D the period was thirty minutes). One purpose of the present study was to investigate the relationship between the effectiveness of the cache and the general type of data contained in the backing store. The volumes being traced were therefore divided into five standard pools according to the general category of data contained on the volume:

- IMS: IMS data base storage.
- CICS: CICS data base storage.
- TSO: TSO user data (in some cases administered by HSM)
- BATCH: Batch application data
- KEY SYS: Control and/or widely shared data central to system operation, including master catalogues, RESLIB data, heavily used program libraries, the HSM and RACF control data sets, the JES2 checkpoint data set, the IMS long and short message queues, and so forth. This category does *not*, however, include page data sets, scratch data sets, spooled data, or IMS logs.

For each category of data at each installation, Figure 1 presents the number of volumes on which data was collected and the average I/O rate of these volumes.

Note that some pools of data contained a very large number of devices. This is a result of the set of standard data pools which were adopted for the purpose of the study. At a given installation, it would have been possible to subdivide any of the various data base or system pools into smaller, more installation-dependent categories. Smaller and more manageable pools would be essential if we were to attempt to do detailed planning for the use of cache at some some particular installation presented in Figure 1. The appropriate partitioning of the volumes of each of the twelve installations into small, installation-dependent categories, however, is beyond the scope of what is being attempted in the present study.

As a result of the use of the standard pool categories shown in Figure 1, we must therefore introduce certain conventions to deal with the possibility of very large pools:

CONVENTION 1: Normal constraints on the maximum number of volumes which may be placed under a cache and/or the maximum cache memory size are not explicitly modeled. Instead, we will compute how much cache memory would be required to handle the activity on each pool of volumes, without regard to size, as though all of this activity were going to a single large cache. (In practice, of course, these volumes would be dealt with in much smaller, application-specific groups).

CONVENTION 2: The computation of the hit ratio is not adjusted to remove write activity from the numerator and denominator. This is due to the problems in obtaining GTF/CCW traces for large numbers of devices. In simulations based on traces of CCW data, the CCW's associated with each I/O are examined to identify those I/O's which cause a write operation to occur. It is then possible to adjust the hit ratio so as to exclude these write I/O's from both the numerator (hits) and the denominator (I/O's to the cache). In a separate preliminary study of this adjustment, however, little if any quantitative difference was found between the adjusted, or "read", hit ratio and the unadjusted hit ratio computed over all I/O's. As a result, the decision was made to perform the present study using SIO traces rather than the full CCW traces. Collection of SIO trace data for all volumes at an installation is efficient and simple; potential problems which might interfere with the

collection of CCW data for so many volumes, such as tape overrun or large amounts of CPU overhead, are avoided. Since CCW data is not included in the trace, however, the unadjusted value of the hit ratio must be used.

Most of the pools presented in Figure 1 contained 3380 devices exclusively. However, some pools (particularly at complexes I, J, and K) contained both 3380 and 3350 devices. To simulate the cache activity of data moved under a cache from a 3350 device, the usual assumption of 2-to-1 mapping was made:

CONVENTION 3: Each pair of adjacent tracks on a 3350 device is assumed to correspond to a single track for the purpose of evaluating cache activity. More specifically, 3350 tracks 0 and 1 are assumed to form one cached track, 3350 tracks 2 and 3 are assumed to form the next cached track, and so forth.

3. THE ROLE OF CACHE RESIDENCY TIME

This section develops in a more concrete and specific way the proposed scheme for projecting the performance of a cache. The starting point for this scheme is the observation that ordinary cache simulation results, which project hit ratios for a range of cache memory sizes, contain hidden information which is worth bringing to the surface. As the memory size is varied over the range adopted for the simulation, there is also an implicit variation in the average residency time spent by a track in the cache. This is what actually causes the hit ratio to change -- the longer a given track stays in the cache, the larger is the probability that it can be reused during its visit.

The quantitative relationship between the cache size and the average time-in-cache can be specified using Little's law, as described in Subsection 3.1. But for the moment, it is worth while to focus on an important qualitative difference between these two parameters: namely, *the relationship between hit ratio and time-in-cache makes sense for every individual track*. We can talk about one single track in isolation from the others. As an extension of this, we can also talk about any specific group of tracks (such as a specific pool of data) in isolation from any other group of tracks. This is impossible when we think of the hit ratio as a function purely of cache size -- the cache size is defined only with respect to the entire cache.

Knowing the average time-in-cache for the cache as a whole does not, of course, mean that we know the average time-in-cache for each individual track; all tracks do not necessarily have the same average residency time. Similarly, all pools which share a cache do not necessarily have the same average residency time. But this caveat is not as damaging as it may seem at first glance.

Suppose, for example, that two pools share a cache. The overall track residency time for either of the two pools is an average of the single-reference residency time (the average residency time for tracks that are referenced exactly once during a given visit) and the multiple-reference residency time (the average residency time for tracks that are referenced more than once). Now, the single-reference residency time is just the average time it takes for a track to migrate from the top to the bottom of the LRU list, assuming that the track is never referenced after appearing at the top of the list. Since tracks from either pool must traverse the same LRU list, both pools must have the same single-reference residency time to a very close approximation. In addition, the residency time for tracks making multiple-reference visits will typically be close to the single-reference time, since the references to these tracks typically occur in a burst. Thus, it is natural to hypothesize that both pools will have average residency times which are, if not equal, at least very close to each other.

Moreover, we shall see in Section 4 that the hit ratio changes only gradually with the time-in-cache. In connection with the reasoning above, this suggests that it may be safe to ignore variations in the individual cache residency times of pools sharing a cache, insofar as they affect the pool hit ratios. Knowledge of the average cache residency time for the cache as a whole may be sufficient to predict the behavior of each individual pool. If we pull together the entire line of reasoning given above, then, we get the following

HYPOTHESIS: Whether a pool is by itself on a cache or shares the cache, the hit ratio experienced by the pool can be predicted as a function of the average cache residency time for the cache as a whole. Except for this relationship, the pool can be treated as being independent of any other pools served by the cache.

This is the hypothesis which the remainder of the paper will pursue. Rather than portraying hit ratio as a function of cache size, we will try portraying it as a function of the average time-in-cache. This information will be developed for each pool for which trace data is available. According to the hypothesis, we should then be able to project the hit ratio as a function of the time-in-cache for a cached controller containing a mixture of two or more pools. This is done merely by projecting the hit ratio for each pool, treated independently, and then aggregating the pool hit ratios to obtain the combined hit ratio for the cache as a whole.

Before diving into details of the study, it is interesting to note that a family resemblance exists between the line of reasoning above and the concept of "working sets" used in the implementation of demand paging [6]. In both cases, the idea is to try to identify how much of a shared memory resource is needed by each individual user of the resource. The strategies necessary in the two situations are rather different, however, since in the case of managing the cache there is no dynamic control over who may use the cache at any given time. Also, there is no mechanism for imposing a specific time window over which the working set is defined. Thus, the issue of consistency of residency times across pools arises, which does not seem to have a direct analogue in the analysis of working sets.

3.1 How it Works

This section describes the specific equations used to implement the game plan described above. The first order of business, in Subsection 3.1.1, will be to lay out the specific relationships which allow us to translate back and forth between cache size and cache residency time. Subsection 3.1.2 then provides the detailed proposal for how we can project the performance of a cache containing a mixture of pools.

3.1.1 Calculating the Cache Residency Time

The first step in any method of predicting the performance of a cache, including the one being proposed, is to collect a GTF/CCW trace of the I/O activity which the cache will support. A simulation tool must then be run against this trace to determine, for a range of possible cache memory sizes, the hit ratio and read/write ratio achievable by the cache for this type of I/O activity.

In the technique being proposed, simulation results of this kind are obtained for each pool i, $1 \le i \le P$, where P is the number of pools. The output of the simulation for each pool contains the projected hit ratios and read/write ratios for a range of possible cache memory sizes. This yields a series of cases, one for each cache memory size, that we can talk about in terms of the following variables. To emphasize that the simulation results are obtained separately for each pool i, each variable is subscripted by the pool number:

M_i = The size of the cache, measured in megabytes.

S_i = The size of the cache, measured in track slots. S_i can be approximated as being a multiple of the cache megabytes. This is not strictly true, due to granularity effects, but it is close enough. A good (slightly pessimistic) rule is that there are twenty-one 3380 (or equivalent) track slots per cache megabyte.

T_i = The average track residency time of the cache

r_i = The I/O rate to pool i during the trace period being examined.

h_i = The hit ratio of pool i during the trace period, adjusted to remove writes from the numerator and denominator. This is the hit ratio usually reported by cache simulation tools.

H_i = The hit ratio of pool i during the trace period, not adjusted to remove writes.

C_i = The read/write ratio of pool i during the trace period, providing that there are writes. If there are no writes, then C_i is not defined.

w_i = The fraction of I/O's to pool i, during the trace period, which are writes. If there are no writes then $w_i = 0$. Otherwise, $w_i = (1 + C_i)^{-1}$

Using these variables, we can now investigate how the cache size relates to the cache residency time T_i. This is done by viewing the LRU list as a queuing system; tracks enter the list, stay for an average period of time T_i, then leave again. Both the rate of entry into the system (the number of read misses per second) and the population of the system (fixed at S_i) are known. Therefore, by Little's law, we have

$$\begin{pmatrix}\text{popu-}\\\text{lation}\end{pmatrix} = \begin{pmatrix}\text{resi-}\\\text{dency}\\\text{time}\end{pmatrix} \times \begin{pmatrix}\text{arrival}\\\text{rate}\end{pmatrix} \tag{1}$$

$$S_i = T_i \times \left[\begin{pmatrix}\text{read miss}\\\text{probability}\end{pmatrix} \times \begin{pmatrix}\text{I/O}\\\text{rate}\end{pmatrix} \right]$$

$$S_i = T_i (1 - h_i)(1 - w_i) r_i$$

or equivalently,

$$T_i = \frac{S_i}{(1 - h_i)(1 - w_i) r_i} \tag{2}$$

For example, suppose that we have just collected a GTF/CCW trace of the TSO user pool at the installation described earlier. The trace covers a period of 15 minutes, and during this period of time the total I/O rate to the pool was 70 I/O's per second. We run a cache simulation against the trace data, and find that during the simulation period the read/write ratio was 9, and that with a cache size of 16 megabytes we can obtain a hit ratio of 85 percent. Now, the cache size of 16 megabytes corresponds to approximately S_{TSO} = 16*21 = 336 track slots; and the fraction of I/O's which are writes is $w_{TSO} = (1 + 9)^{-1}$ = 10 percent. Therefore, we calculate from (2) that

$$T_{TSO} = \frac{336}{(1 - 0.85) \times (1 - 0.1) \times 70} = 35.6 \text{ seconds}$$

If this reasoning is repeated for a range of cache sizes, then a chart of hit ratio as a function of time in the cache is obtained for the TSO pool. This is the technique used in Section 4 to develop the charts presented by Figures 2 - 5. These charts show hit ratio as a function of time in cache for each pool included in the study.

In the case of the pools traced in the present study, the values of w_i are not known accurately due to the use of SIO, rather than CCW, traces. It *is* known, however, that the values of w_i are small, since these pools do not contain any scratch, spool, paging, or IMS log data. As a rough approximation, we set $w_i = 0$ in (1) and (2), and use H_i in place of h_i. This results in a small error in computing the time-in-cache corresponding to a given hit ratio. Since it affects a given pool in the same way whether the pool is by itself or on a mixed cache, however, a small error of this kind does not interfere with our ability to test the hypothesis of the paper. As shown in Section 4, hit ratio estimates are insensitive to this form of error in any case; the hit ratio changes only gradually with the time in cache.

3.1.2 Estimating the Performance of a Mixed Cache

Once a chart is available for each pool showing hit ratio as a function of time-in-cache, we are ready to develop a chart for the case of any desired combination of pools. The idea is to combine the charts for several pools sharing a cache through ordinary averaging. Since the hit ratio is defined as a fraction of read I/O's, the average must be weighted by the read I/O rate.

More formally, suppose that the quantities r_i, w_i, and C_i, and the functions h_i and S_i of T_i, have been obtained for each pool i, $1 \le i \le P$. Given a cache in which these pools are combined, we are now able to compute the aggregate I/O rate $r_\bullet$, the aggregate fraction of writes $w_\bullet$, and the aggregate read/write ratio $C_\bullet$. In addition, we are able to compute estimates $h_\bullet$ and $S_\bullet$ of the aggregate hit ratio and aggregate cache memory size as functions of the overall cache residency time $T_\bullet$.

The combined I/O rate, of course, is

$$r_\bullet = \sum_{i=1}^{P} r_i \tag{3}$$

Since mixing of the pools has no effect on each pool's pattern of reads and writes, it is also immediate that

$$w_\bullet = \frac{1}{r_\bullet} \sum_{i=1}^{P} r_i w_i \tag{4}$$

and, assuming that there are writes,

$$C_\bullet = \frac{1 - w_\bullet}{w_\bullet} \tag{5}$$

Finally, we must develop a chart of hit ratio versus time-in-cache for the combined pools. The hypothesis of independent pool behavior is used to estimate the individual hit ratio and corresponding memory requirements of each pool within the combined cache:

$\hat{h}_i$ = the value of h_i which corresponds to a time-in-cache equal to $T_\bullet$, as specified in the the chart of hit ratio data previously obtained for pool i by itself.

$\hat{S}_i$ = $T_\bullet (1 - \hat{h}_i)(1 - w_i) r_i$ = the memory requirement of pool i obtained by plugging this hit ratio into (1).

The aggregate hit ratio is then obtained as a weighted average of the individual pool estimates:

$$\hat{h}_\bullet = \frac{1}{r_\bullet (1 - w_\bullet)} \sum_{i=1}^{P} r_i (1 - w_i) \hat{h}_i \tag{6}$$

If the quantities $\hat{h}_i$ were replaced by measured hit ratios on the combined cache, then (6) would yield the exact value of the aggregate hit ratio. The major point of the paper, however, is that these measurements on the combined cache are *not needed*. The simulations of each pool by itself provide a sufficient amount of data to produce sound estimates.

The total memory requirements of the combined cache can be estimated either as the sum of the estimated requirements for each pool, or by another application of Little's law:

$$\hat{S}_\bullet = \sum_{i=1}^{P} \hat{S}_i \tag{7}$$

$$= T_\bullet (1 - \hat{h}_\bullet)(1 - w_\bullet) r_\bullet$$

It can be shown that these two methods of calculation are equivalent.

Example:

Consider a cache in which the TSO pool described earlier is combined with the KEY SYS pool. By analyzing each pool individually as described in Subsection 3.1.1, we estimate that that if the cache residency time is 30 seconds, then the TSO and KEY SYS pools can achieve hit ratios of 84 and 93 percent respectively. The I/O rates of the two pools during the trace period were 70 and 50 I/O's per second respectively, and the read/write ratios were 9 and 6 respectively. Corresponding to the read/write ratios of 9 and 6, the fractions of write activity for the two pools are $(1 + 9)^{-1}$ = 0.100 and $(1 + 6)^{-1}$ = 0.143 respectively.

We begin the analysis of the planned cache by computing the aggregate I/O rate and read/write ratio according to equations (3) - (5):

$$r_* = 70 + 50 = 120$$

$$w_* = \frac{1}{120}(70 \times 0.100 + 50 \times 0.143) = 0.118$$

$$C_* = \frac{1 - 0.118}{0.118} = 7.47$$

Based on the data collected for each pool by itself, we estimate that for a mixed cache with a residency time of $T_* = 30$ seconds, we can obtain hit ratios of

$$\hat{h}_{TSO} = 0.84$$

$$\hat{h}_{KEY\,SYS} = 0.93$$

By (1), the memory requirements corresponding to these hit ratios are

$$\hat{S}_{TSO} = 30 \times (1 - 0.84) \times (1 - 0.100) \times 70 = 302 \text{ track slots}$$

$$\hat{S}_{KEY\,SYS} = 30 \times (1 - 0.93) \times (1 - 0.143) \times 50 = 90 \text{ track slots}$$

Using these hit ratios and storage requirements for each component of the activity, we can now use (6) and (7) to estimate the hit ratios and storage requirements overall:

$$\hat{h}_* = \frac{70 \times (1 - 0.100) \times 0.84 + 50 \times (1 - 0.143) \times 0.93}{120 \times (1 - 0.118)} = 0.877$$

$$\hat{S}_* = 302 + 90 = 392 \text{ track slots} = 18.7 \text{ MB}$$

Since a cache controller cannot be configured to have a size of precisely 18.7 MB, we must choose either the next size down or the next size up. The required memory size is probably close enough to 16 MB so that good performance can still be achieved by a 16 MB cache -- but this would not leave any room for future growth in the workload. Alternatively, we might choose a 32 MB cache. In this case the cache performance will exceed requirements (not necessarily a bad outcome), since the average time-in-cache will be greater than the required 30 seconds. Another idea might be to try caching an additional small pool of data, such as the decision support system. The resulting combination of three pools might take greater advantage of a 32 MB cache.

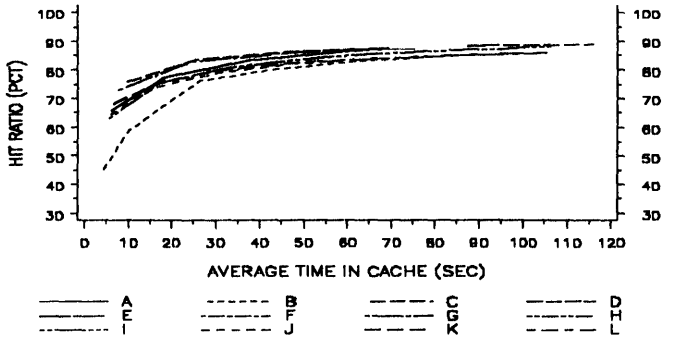

Figure 2. Hit Ratios for CICS Pools

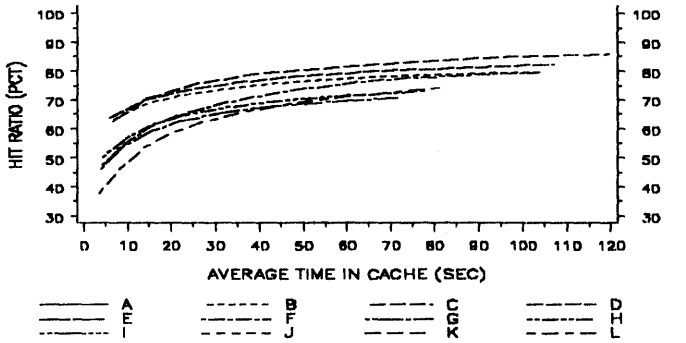

Figure 3. Hit Ratios for IMS Pools

4. A NEW VIEW OF HIT RATIO DATA

The next step is to try out the idea of plotting hit ratio as a function of time-in-cache. Figures 2 - 6 present the results of the analysis described in Subsection 3.1.1 as applied to the CICS, IMS, TSO, BATCH, and KEY SYS pools respectively. The data for each pool observed at a given installation is shown by a specific curve, which is identified by the letter for the installation as defined in Figure 1.

These hit ratio curves exhibit a number of interesting features. Note particularly that each curve seems to have a "knee" at or near a cache residency time of 20 seconds. An effect of diminishing returns begins to set in by the time the curve reaches 30 seconds, and there seems to be relatively little benefit associated with increasing the time-in-cache beyond 60 seconds. (An exception to this pattern may be the BATCH pools, which seem to show relatively less responsiveness to an increase in the cache residency time compared to the other pools).

Another important feature of the hit ratio curves is the degree of consistency which seems to exist for data of the same type across various installations. This is particularly true toward the right-hand side of each chart. At a time-in-cache of 60 seconds, it seems that we should be able to expect, with reasonably high confidence, that a CICS pool can achieve a hit ratio of 82-87 percent; an IMS pool can achieve a hit ratio of 70-82 percent; a TSO pool can achieve a hit ratio of 84-93 percent; and a KEY SYS pool can achieve a hit ratio of 84-94 percent. The performance of BATCH data seems more uncertain; this is probably dependent, among other things, upon the blocking of the portion of the BATCH data which is sequential.

Finally, it should be noted that in the region past about 20 seconds, the hit ratio is a gradual, rather than a highly sensitive, function of the cache residency time. This bodes well for the hypothesis offered earlier in the paper. If the average residency times for two pools sharing a cache are slightly different, and if we ignore the difference between the two, this would cause only a very small error in the resulting estimates of the pool hit ratios.

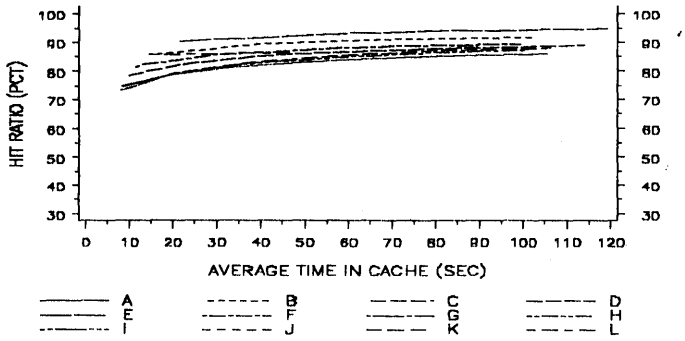

Figure 4. Hit Ratios for TSO Pools

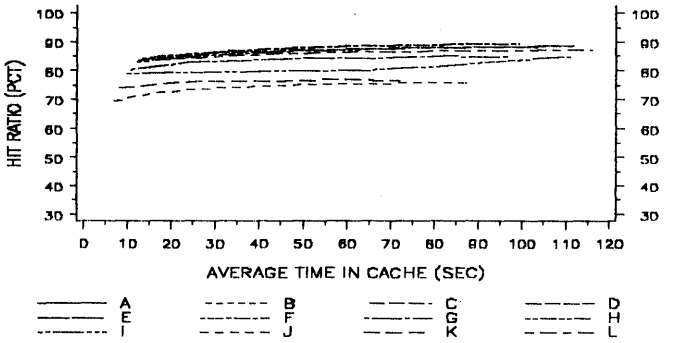

Figure 5. Hit Ratios for BATCH Pools

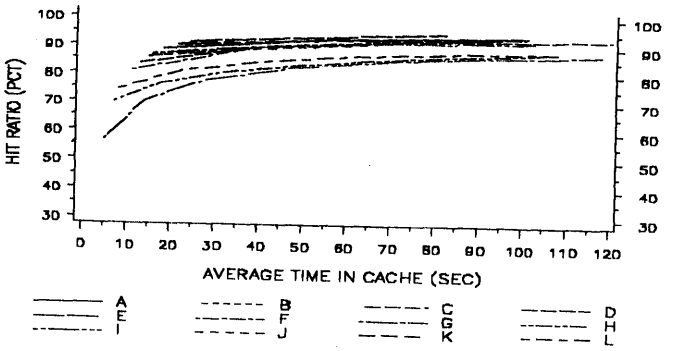

Figure 6. Hit Ratios for KEY SYS Pools

5. TEST RESULTS

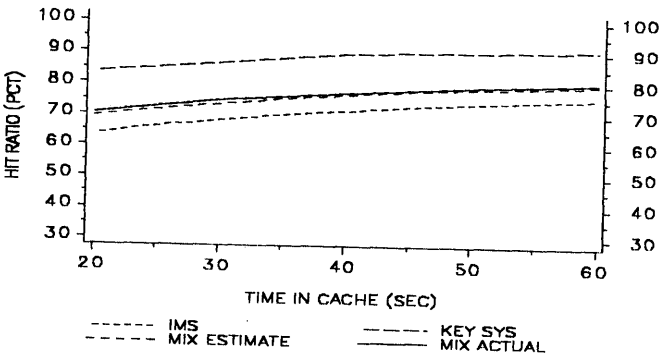

Figure 7. Predicted and Actual Mixed Pool Hit Ratio: KEY SYS and IMS Pools at Complex F

With the data of Figures 2 - 6 in hand, we are now able to test the hypothesis of Section 3. The approach to testing is based on (6) -- i.e., we will estimate the hit ratio of a mixed cache as though the hit ratio of each pool were an independent function of the cache residency time T_c. We will then see if this estimate is accurate enough so that (6) holds.

Note that for the purpose of testing the hypothesis of independent pool behavior, the definition of a pool is arbitrary. Two pools A and B can be treated as a single combined pool A + B if we wish. There is no physical distinction between these two methods of grouping the same data. Thus, it suffices to test the hypothesis for groups of two pools. The hypothesis can then be applied to larger numbers of pools simply be redefining the pool groupings.

The method of testing is illustrated in Figure 7. The top and bottom curves of the figure show the relationship of hit ratio versus time-in-cache for the

KEY SYS and IMS pools respectively at complex F. The dashed curve in the center shows the predicted hit ratio if these two pools were combined on the same cache, derived using (6). The solid line shows the actual hit ratio which was obtained by merging the I/O traces for the two pools and running a cache simulation against the merged trace. As the figure makes clear, very little error is introduced through the use of (6).

Figure 8. Tests of the Pool Independence Hypothesis

Figure 8 presents all 16 specific pairs of pools which were selected for the purpose of testing the pool independence hypothesis. The criteria used in constructing these pairs were,

1. Contrasting types of activity, and
2. Reasonable balance in the I/O rates (so that each pool would make some contribution toward the average hit ratio).

The figure shows the predicted hit ratio for each pair of pools at residency times of 20, 30, and 60 seconds, obtained from (6). For each pair of pools, a cache simulation was run against the merged trace. The error following each predicted hit ratio in Figure 8 is the difference between the predicted hit ratio value and the result of this simulation (the actual result of the simulation is not shown explicitly, but can be obtained by subtracting the error from the predicted value). The figure also shows the maximum difference, in the range $20 \leq T \leq 60$, between the predicted and actual hit ratios for each case. The errors in the predicted hit ratio never exceeded 1.4 percentage points for any of the test cases. Note also that the actual hit ratio is always slightly *better* than the estimated hit ratio. Thus, the prediction obtained from (6) is not only consistently accurate, but is also slightly conservative.

6. CONCLUSION

The main conclusion of the paper is that the hit ratio of each pool in a mixed cache can be estimated as an independent function of the average cache residency time. In addition, the cache residency time is closely related to the cache memory size due to Little's law.

The ability to treat the pools in a mixed cache independently is of great practical interest, and it is also satisfying from a conceptual standpoint. It clarifies the link between hit ratio and locality of reference. Since locality of reference is a characteristic of individual data sets and collections of data sets, the behavior of the hit ratio should be also. We have shown that the hit ratio can, in fact, be analyzed in this way.

The key to the approach is that hit ratio must be treated as a function of the average time which a track spends in the cache. Due to the LRU mechanism, and also due to the tendency of I/O to a given track to come in bursts, the average times-in-cache of multiple pools sharing a cache tend to be close to each other -- close enough so that for practical purposes, the differences between them can be neglected. Thus, the hit ratio of each pool in the cache can be treated as an independent function of the average cache residency time.

This situation leads to a simple and practical scheme for comparing large numbers of possible cache configurations so as to better understand the potential benefits which might result from the use of cached controllers. As shown by the empirical results which we have obtained, the hit ratio estimates which the technique provides are very accurate.

WORKLOAD CHARACTERIZATION FOR SUBSYSTEMS: A CASE STUDY FOR IDMS

Ellen M. Friedman
SRM Associates, Ltd.

ABSTRACT

There has been a significant increase in the number of installations utilizing Cullinets IDMS database system in recent years. Most of these installations use CICS/VS for data communication and interface with IDMS/DB through an SVC. Unfortunately, the available techniques for analyzing IDMS performance and capacity issues has not kept pace with this growth in new applications.

This paper presents a methodology for workload characterization for subsystems with the particular emphasis placed on IDMS applications. We will discuss the data collection and analysis tools available for performance analysis and workload characterization studies. In addition, factors critical to IDMS on-line performance will be highlighted and the differences between using CICS and IDMS for data communication will be reviewed. A case study detailing the methodology and analysis process is presented.

Introduction

The number of installations utilizing IDMS/DB has increased significantly in recent years. However, the information concerning IDMS performance analysis and capacity planning has not quite kept pace with this increased usage.

IDMS, like other TP systems is not necessarily comprised of a set of transactions or run-units which are homogeneous with respect to their consumption of computer resources. Therefore, we propose a methodology for profiling transactions/run-units based on resource utilization parameters to facilitate the construction of homogeneous workloads. The methods and techniques we will discuss in this paper can aid the capacity planner to better understand resource usage for any subsystem and in particular, for IDMS workloads.

Yogi Berra once expressed, "You can observe a lot by watching". In other words, in order to know what's happening in the subsystem you have to look at it. Workload characterization is the process of analyzing a set of data in order to understand the relationship between resource usage, transaction arrival rate and workload mix on system performance. It is the process of forming homogeneous workloads consisting of similar transaction/run-unit resource profiles. The results of such studies will enable the analyst to formulate an accurate and meaningful representation of the workloads comprising the system.

Background- IDMS/R

IDMS/R, a Cullinet relational DBMS, manages the flow of information between application programs and the database. It can operate in both "Local" and "Central Version" mode. While executing in Local mode, only one application program at time can access the database. The Central Version (IDMS-CV) provides multi-programming capability; allowing multiple concurrently executing application programs to access the database using a single copy of the DBMS. As a result, the use of IDMS-CV is preferable in most environments. Central Version operations are also required for application programs which execute under a teleprocessing system (TP). If a TP system other than IDMS-DC is used, an interface module tailored to the specific TP monitor is set-up to be shared by all teleproccessing application programs.

IDMS-DC is an extension of the IDMS-CV providing all of the CV capabilities, as well as controlling the data communications environment which maintains the teleprocessing services necessary for on-line transaction execution. In addition, a Universal Communications Facility (UCF) is provided which allows on-line application programs to be executed from terminals controlled by a TP monitor, while providing all the services of IDMS-DC. UCF is an interface that supports CICS, SHADOW, INTERCOMM, TASK MASTER, WESTI, IDMS-DC, TSO AND CMS.

For the purposes of detailing the workload characterization methods, we will restrict the discussion to the IDMS-CV (the multiprogramming version), and consider both IDMS-DC usage and CICS-DC with the UCF interface [Ref. 1,2,3,4].

General Methodology for Workload Characterization- Subsystems

The workload characterization process requires a representative sample period and relevant performance measurement for analysis. The time varying nature of workload resource usage, and the dependencies upon particular workload mix and arrival rates which impact system performance must be considered as part of the characterization process.

For MVS systems, resource consumption information can be determined on a performance group basis from RMF/SMF data. Average resource profiles can be constructed for each region/performance group in terms of their relative usage of CPU, I/O and memory service. By examining graphs of these average resource profiles over time, we can determine which time periods to use as a sample for a more detailed characterization analysis. In the case study, we discuss the use of such graphics as part of a general data gathering and knowledge acquisition process which is key to developing a realistic and representative characterization of the workloads.

In studies of capacity planning, forecasting and analytic modeling efforts are usually performed for "peak periods". A determination of "typical or representative sampling intervals can be made by examining the sampled distribution of several critical performance variables. Extreme intervals, or intervals containing performance exceptions should be eliminated when performing studies of workload characterization.

When the sampling process is complete, transaction profiles based upon resource consumption can be developed for the selected samples. The construction of transaction profiles is highly dependent upon the particular subsystem we are examining. In a previous paper, we outlined some of the significant variables critical to CICS/VS performance which should be used when classifying CICS work [Ref. 5]. The process of determining those variables which are critical to

performance and are also indicative of resource usage may not be as obvious for all subsystems. Generally, we determine resource usage based upon CPU, and some indication of memory and physical I/O counts. Later in this paper, we will discuss which performance variables we found to best define resource usage in our characterization of IDMS.

Cluster Analysis

The objective of the workload characterization process is to define those key elements which accurately describe the resource consumption of the workload. The general classification approach is to form workloads that are mutually exclusive and internally consistent; that is, the variability within a workload or group should be less than the variability observed between workloads or groups. One popular approach to the problem of forming homogeneous workloads is to utilize cluster analysis based upon a subset of the resource consumption variables.

Given a number of objects, each of which is described by a set of numerical measurements, the objective of cluster analysis is to devise a classification scheme for grouping the objects into a number of classes such that objects within classes are "similar" in some respect and unlike those from other classes. In the case study, we will utilize clustering techniques to form groups of transactions/run-units using their description as defined by the resource consumption variables. The initial choice of the particular set of measurements used to describe each observation constitutes the frame of reference within which to establish the clusters. The choice of measurements reflects the analysts judgment of their relevance to the classification process.

There are several important decisions to be made before inputting a set of data to a clustering algorithm these include:

- How many variables are desirable and practical?
- Which variables to include?
- Are the variables correlated with each other?
- Should the data be standardized in some way to minimize the impact of measures on different scales?
- What is the optimal number of clusters?

It is quite apparent that the choice of input variables will determine the resulting classification, and different groupings may arise as a result of using unstandardized rather than standardized data. The variables are usually standardized, since many of the clustering algorithms are sensitive to variables measured on different scales. A potential danger in using these algorithms, without first adjusting the variables to the same scale, is to artificially give greater weight to those measures (variables) exhibiting greater variability in the algorithm (e.g. storage measured in K Pages vs. CPU measured in msec). In addition, determining the optimal number of clusters for any given data set remains an outstanding problem in the application of clustering techniques. There is a vast amount of literature which discusses these issues. A good introduction can be found in Brian Everitt's text entitled Cluster Analysis [Ref. 6], as well as a brief overview in the SAS Statistics User's Guide [Ref. 7]. In the case study, we will discuss the techniques used to determine homogeneous workloads; including a discussion of sample selection, variables selection, standardization issues and determining the number of groups. We will also review the SAS procedures employed in our analysis. In the case study, we used FASTCLUS, CLUSTER, canonical discriminant analysis and principle components to aid in the determination of the grouping of run-units.

Workload Characterization for IDMS/CV

Data Collection

At the performance group/region level, RMF/SMF data can be used to obtain overall resource consumption information. In addition, the IDMS/R performance monitor (IDMS/R-PM) can be used to capture and record task performance information for IDMS-DC/UCF tasks, an ADS/On-Line dialog, an External Run Unit (ERUS) or CICS transactions external to IDMS-DC-UCF. The IDMS/R performance monitor records can be stored on the SMF file as a user SMF record type NNN (usually written as an SMF 230 record). The SMF header contains the SYSTEM ID, and date-time stamp information. The RT1 record (also referred to as the IDMS/R-PM record) contains information concerning database activity, program type (IDMS/DC , CICS etc.), terminal activity, and CPU and memory resource usage by task/run-unit [Ref. 1]. The IDMS-DB/DC Transaction Statistics can be found in Table I.

IDMS Workload Analysis

To properly characterize the IDMS/CV, we must profile transactions or run-units in terms of their usage of memory, CPU requirements and database activity. In addition, we must first qualify whether the program or dialog was executed under IDMS/DC-UCF, CICS-DC, Batch or some other TP monitor. We must also distinguish between internal IDMS-DC and other TP monitor system tasks, and user tasks. Since ADS/On-line dialogues are inherently more resource intensive than normally generated Cobol or PL/1 programs, we should further identify the run-units according to the DC tasks, first-level programming language.

There is an inordinate number of statistics collected for each IDMS transaction; however, not all of these are immediately concerned with resource consumption nor are they all useful as performance indicators. We will discuss that subset of variables which we have found to be useful in characterizing the transaction set for the case study. In a different IDMS environment, the variables which we excluded from our analysis might have played an important role in characterizing the system. This is due to the fact that the workload characterization process is environment dependent. Generally, however, we characterize the transactions/run-units based upon measures of CPU, I/O and memory usage. A brief discussion of the performance concerns for IDMS systems can be found in the IDMS-CV/DC Systems Operations Guide [Ref. 2, Section 5].

In order to characterize the IDMS system in terms of resource usage, we need to examine CPU consumption, memory or storage utilization and some indication of logical and physical I/O usage.

CPU

Using information from RMF, we can determine the total CPU utilization for a particular performance group/IDMS region. In addition, the IDMS performance record (SMF 230) provides the total TCB time used by each run-unit. This time totaled across all run-units should match the TCB time recorded in the RMF TYPE 72 record for the entire region. Unlike CICS monitor data, the SMF 230 records reports on both task or user TCB time, as well as the amount of system time (including scheduling, terminal handling etc.) used by the run-unit. It should be noted however, that this decomposition of System CPU Time and Task CPU Time is only recorded if a parameter in the SYSGEN is set. Otherwise, all of the TCB time for the task is reported as System CPU time. cIn the case study, the task TCB time is not decomposed and the total TCB time is recorded as System CPU.

I/O

The SMF TYPE 30 records provides the total number of EXCP's used by each performance group/region. The IDMS performance record additionally provides the number of physical I/O's for each run-unit. The total I/O count for each run-unit = the Number of Page Reads + the Number of Page Writes. In addition, the record contains the number of records requested, the number of database calls, the number of pages requested, an indication of poor page size and buffer management, and the number of database locks held by the task.

In order to determine the best subset of these variables to utilize in the classification process, we examined the distribution of each of these variables and examined their relationship with CPU time and elapsed time. Since, we did not want to include variables which were highly correlated with each other, we also reviewed their interdependencies and correlations (specific details are discussed in the case study).

Memory/Storage

From RMF, one can compute a memory occupancy factor (total number of pages used based on MSO service units) for each region/performance group. In addition, the IDMS performance record gives an indication of each run-units usage of storage. The measures include: the amount of storage used from the storage pool (IDMS/DC storage), the amount of storage used from the program pool, and the amount of storage kept from the storage pool. In addition, the number of storage GETS and Puts is recorded. Since storage is also affected by the use of many programs and whether or not those programs are already resident, we also must consider the number of programs called and the number of programs loaded.

Other Classification Variables

Other performance variables may also be used in the classification process to distinguish one set of transactions (run-units) from another. For example, the number of bytes read/written from/to the terminal is an indicator of line utilization. Further, the number of levels doing DB work can be used as a measure of the level of program complexity.

We also examined scatter plots of these variables against elapsed time and CPU time, and their correlation with other indicators of resource usage.

Other IDMS Performance Concerns

The size of each program pool will determine the amount of storage available to the IDMS-CV/DC for loading non-resident modules. The maximum number of tasks and external run-units active and the size of storage pools will impact the total amount of storage required.

The number of database key locks maintained by an IDMS system can impact CPU usage. The efficient use of buffer pools will also contribute to system performance. Factors often considered are the ratio of PAGES REQUESTED/ PAGES READ (logical to physical I/O ratio), the ratio of RECORDS REQUESTED/ NUMBER OF RECORDS CURRENT FOR RUN UNIT; these ratios should not be that high.

In any on-line database system, the database and DASD configuration can tremendously impact the resulting performance. In an IDMS/R database structure, the database is stored physically as one or more data sets on DASD and can be accessed using BDAM, DAM, VSAM or UPAM [Ref. 3]. Each database area corresponds to a portion of a file stored on DASD. These areas defined in a database can be such that either a) all areas map to a single file, b) each area can be mapped into a different file, or c) one area can be mapped into several files. As a result, the number of EXCP's recorded for a particular file/DDNAME may be a result of database usage from a single area or from a portion of many different areas. It is therefore difficult to tune the I/O subsystem based solely on RMF/SMF DASD and file utilization information.

The database structure and the resulting number of physical I/O's will depend upon how the database administrator has mapped these areas to DASD. As such, to minimize any I/O bottlenecks, the database administrator or performance analyst should attempt to correlate the database statistics provided by the IDMS performance monitor with the DASD and file utilization information that can be derived from RMF/SMF.

Case Study

Overview

The formulation of an accurate and meaningful representation of system workloads is a desired goal of the capacity planning process. The following case study serves to exemplify the workload characterization process. The analysis was performed using graphic techniques, by examining the distribution of the important performance variables, and using cluster analysis methods.

Description of System

As a case study, several days of RMF, SMF and IDMS performance measurement data were examined for a large IDMS system environment. The CPU was a 3090-200 with 64 megabytes of real memory and 64 megabytes of expanded storage executing under MVS/XA. The processing environment consisted of 5 large production regions running under Release 10.0 of IDMS/R , one stand-alone production CICS region and some minimal batch work. The daily peak processing hours for the system were between 11:00-12:00 in the morning and 1:30 to 5:00 in the afternoon. During these hours the system was approximately 85% busy, with the majority of the activity attributable to three of the IDMS regions.

Data Analysis

Workload Characterization by Region

The RT1 performance reports were reviewed weekly, for each of the IDMS regions to determine the average number of transactions processed per hour, average response times and average transaction resource usage by region. In addition, we examined the resource usage of individual IDMS transactions to determine whether they constituted a homogeneous group.

In Figures I and II, we have included a decomposition of the CPU busy by each of the major workloads for two different sample periods. Average CPU busy was graphed hourly to display the variation in utilization across the on-line day. The data indicates that the peak processing time is fairly consistent between 11:00-12:00 and 1:00-5:00 P.M.

Using data stored in a SAS database, in conjunction with overall IDMS workload statistics, we were able to identify typical average and peak resource usage patterns. Graphs comparing the average resource profiles of each of the IDMS regions (constructed for peak hours) can be found in Figures III and IV. These profiles are defined in terms of average CPU, and DASD service requirements. The service time profiles are measured in terms of milliseconds per transaction and do not include queuing delays.

An examination of these graphs suggests that the IDMS1 (I1) region is significantly different from the others. The CPU requirements per transaction are almost twice that of the other regions (Figure V). A comparison of the average resource profiles constructed for each of the regions between September and December indicates a change in decomposition. This suggests that changes in workload mix and arrival rate may have been responsible for the differences observed in average resource profiles.

The graphs we have selected are only a sample set, other periods of time were also examined to determine whether an "average transaction" could be constructed to serve as a typical measure for use in trend analysis and analytic modeling. Since the data suggested variability in average resource usage for each of the regions, it was necessary to further decompose each region in terms of groupings of homogeneous run-units/transactions. Using average profiles constructed for these groups, trending and analytic modeling could be performed with greater accuracy.

Workload Characterization- Detailed

A sample peak period consisting of the hours of 1:00-5:00 P.M. on two separate days was selected to analyze the average resource consumption of each of the run-units. For illustrative purposes, we have reduced the problem to forming homogeneous workload groupings for only one of the IDMS regions (IDMS1).

The distribution of all resource parameters critical to performance was examined for the region. In addition, we examined the relationship between these variables and both CPU consumption and elapsed time. The variables we examined included all of the database statistics, and terminal, storage and program information. We also examined the correlations between these variables, so that the total number of variables could be reduced to a set of uncorrelated variables containing the same level of information as the original. The preliminary subset of variables we examined included:

- CPUtime
- Number of Physical I/O's
- Number of Records Requested
- Number of Pages Requested
- Number of Database Requests
- Length of Terminal Read (in bytes)
- Length of Terminal Write (in bytes)
- Number of Programs Loaded
- Number of Programs Called
- Number of VIA records with Oflow
- Number of VIA records without Oflow
- Amount of Storage Used from Storage Pool
- Amount of Storage Used from Program Pool
- Number of Levels doing DB work
- Number of Records Current of Run Unit

Based upon the resource information from this preliminary set of variables, the task is to form a set of homogeneous groupings of transactions/run-units. The first step was to decompose the region by program type, as we were not interested in classifying system transactions, and resource intensive ADS/ON-LINE transactions with the general population of user tasks. Given this initial decomposition, we used a combination of clustering techniques, and principal components to form groups of user tasks/run-units. Once these clusters were formed, we used canonical discriminant analysis to describe the groups in terms of the original variables.

Overview of the SAS PROCEDURES

In the case study, we utilized FASTCLUS, CLUSTER, canonical discriminant analysis and principle components to aid in determining the grouping of run-units. The SAS FASTCLUS procedure finds disjoint clusters of observations using Mac-Queen's K-Means algorithm. It is designed to handle very large data sets with relatively few passes through the data. There are many other programs available to perform cluster analysis, many of which are published [Ref. 10]. We have chosen to restrict our discussion to the SAS procedures, as they are more widely available to the data processing community and the newest release of SAS (1985) has been updated to reflect recent advances in the field.

The FASTCLUS procedure requires the user to input the maximum number of clusters or groups to be classified. Since one may not know how many groups optimally describe the data points, this process could require several iterations. At the end of each iteration, the clusters are evaluated by certain "Goodness-of-Fit" criterion. As output, FASTCLUS provides several statistics for each variable including: an R-Squared value for predicting the variable from the cluster, and the ratio of between cluster variance to within cluster variance. In addition, it provides a statistic called the Cubic Clustering Criterion (CCC) which can be utilized to determine the number of clusters. (Note: This statistic is an approximation to the expected value of R-Squared and SAS indicates that the formula they used to compute it may change in future releases).

At the end of each run, the CCC and R-Squared values are recorded along with the number of clusters. The analyst typically will run the program for cluster groups ranging from 1 through 25. Alternatively, the analyst can run the CLUSTER procedure which automatically produces the CCC and R-Squared statistics for values of one cluster up to as many as desired, in a single run. Plots of both of these statistics can be generated to determine the number of groups. When the Cubic Clustering Criterion is plotted against the number of clusters, peaks on the plot greater than 2 or 3 indicate good clusters. The Cluster procedure also prints pseudo F and T^2 statistics. These values can also be plotted against the number of clusters, peaks on the plot are an indication of the number of clusters yielding good separation. The pseudo T^2 statistic can be used by looking for large values and taking the number of clusters to be one greater than the level at which the peak occurred.

The first stage in many cluster analyses is to convert the raw data matrix into a matrix of inter-individual "similarity", or distance measures (i.e., measures of how alike the groups of transactions are). Using FASTCLUS, the clustering is done on the basis of Euclidean distance measures computed from the variables.

The initialization routine used by FASTCLUS makes it sensitive to outliers. As such, it can be an effective method for detecting outliers, as they often appear as clusters containing very few members. Once the outliers are removed from the data set, the FASTCLUS procedure can be reinvoked with a reduced number of clusters. The goal is to choose the smallest number of groups which describe the data with greatest accuracy.

The test statistic, the CUBIC CLUSTERING CRITERION requires the variables to be uncorrelated. If the variables are correlated, we must first perform a principle component analysis to reduce the dimensionality of the problem. Each principle component is defined as a linear combination of the original variables and they are jointly uncorrelated.

The FASTCLUS procedure was utilized to form a preliminary set of clusters. The Cluster procedure was then used to hierarchically cluster the observations. The clustering methods available are average linkage, the centroid method, complete linkage, density linkage, maximum likelihood for mixtures of multivariate normal distributions with equal variances but possibly unequal mixing proportions, the flexible-beta method, McQuitty's similarity analysis, the median method, single linkage, two-stage density linkage, and Ward's minimum variance method. All of these methods are based on agglomerative hierarchical clustering procedures [Ref. 10].

Using agglomerative hierarchical clustering methods, each observation initially begins in a cluster by itself. The two closest clusters are merged to form a new cluster which replaces the old cluster. The process of merging clusters is repeated until only one cluster remains. The major difference between the clustering methods is in the choice of the distance measure.

In the case study, we used average linkage, density linkage and Ward's minimum variance method. In average linkage, the distance between two clusters is defined as the average distance between pairs of observations, one in each cluster. The density linkage method (Wong and Lane 1983), refers to class of clustering methods using nonparametric density estimates. The distance measure, or dissimilarity measure is defined as the reciprocal of an estimate of the density midway between two adjacent observations x_i and x_j. We used Wong's hybrid clustering method which uses density estimates based on the preliminary cluster analysis from FASTCLUS (a k-means method). Using this method, two clusters C_k and C_l are considered adjacent, if the midpoint between their cluster means $\bar{x}_k$ and $\bar{x}_l$ is closer to either $\bar{x}_k$ or $\bar{x}_l$ then to any other cluster mean. As output, the density linkage method will print the number of modal clusters, where the number of modal clusters formed is an indication of the optimal number of clusters or groups.

Cluster Analysis Process for the IDMS workload

To avoid the potential problem of using variables measured on different metrics, we standardized each of the variables to a mean of 0 and standard deviation of 1. (This standardization is often referred to as forming a Z-Statistic and can be easily accomplished using PROC STANDARD). The standardized data was used in all subsequent analyses.

Using the SAS FASTCLUS procedure, we formed an initial grouping of run-units. Our objective in this first run was to remove the presence of outlier observations, where we defined outliers as clusters containing less than 5 observations. Given a reduced set of observations, we could then proceed to determine the optimal number of classes to best describe the set of run-units.

A preliminary set of clusters was produced using FASTCLUS with a maximum number of clusters equal to 25. The cluster summary statistics from this initial run can can be found in Table II and Table III. The information displayed in Table II was used to identify those groups with fewer than 5 observations. The data presented in Table III provides summary statistics for each of the variables including the R^2 value for predicting the variable from the cluster, and the ratio of between cluster variance to within cluster variance. After removing the outlier values, we reinvoked the FASTCLUS procedure with 22 clusters and observed that one of the groups, "Cluster 20" was significantly different from the others (TABLE IV). Therefore, since we had already confirmed that this group was significantly different from the other's, we deleted it and reinvoked the FASTCLUS procedure with 21 clusters in order to pursue the identification of differences amongst the remaining observations.

An examination of the correlation matrix suggested that many of the variables were correlated. We therefore had several options in our analysis. One option was to examine the principle components and select those variables with high loadings (i.e. those variables corresponding to large coefficients for the eigenvectors) that are also uncorrelated with the other variables selected. As a second option, we could choose the first few principle components which explained over 80% of the variance as input to the cluster procedure. (The principle components are linear combinations of the original variables and are jointly uncorrelated).

To summarize up to this point, there are several factors to consider in the analysis, one is to remove the presence of outlier observations which can obscure any underlying differences between observations and groups. The second critical factor is to identify the important variables to include in the cluster analysis. In our analysis we actually went through several iterations, "boot-strapping" our way through the problem of identifying groups and variables. We used an initial set of variables as input to the FASTCLUS procedure and identified the outlier values. Once the outliers were removed, we were able to concentrate our analysis on identifying the important variables. The selection of variables is a critical step in forming homogeneous groups of observations. Not all of the steps in our analysis have been detailed, we have included the major portions to highlight the process.

In Table V, we have included the principle components and their coefficients. The first principle component has high positive loadings for data base usage, the number of physical I/O's and CPU. The second principle component exhibits high positive loadings for storage usage, both program and storage pool, and on the number of programs called. The first five principle components account for 80% of the variation.

As a result of the various analyses we performed, the following variables were selected as input to the CLUSTER procedure:

- CPUtime
- Number of Physical I/O's (IOCOUNT)
- Number of Database Requests (RT1DBDBC)
- Length of Terminal Read (in bytes) (RT1DCTRL)
- Length of Terminal Write (in bytes) (RT1DCTWL)
- Number of Programs Loaded (RT1DCNPL)
- Amount of Storage Used from Storage Pool (RT1DCSUS)
- Number of Levels doing DB work (RT1DCCUR)
- Number of Records Current of Run Unit (RT1DBRCR)

It should be noted that at one point, we also included the number of VIA records with and without overflow. We found however, that the cluster procedures yielded better separation between groups when these variables were left out of the analysis.

We used three different methods from the CLUSTER procedure to hierarchically cluster the preliminary clusters produced by FASTCLUS; Ward's minimum variance method, average linkage, and density linkage. For each of these methods we also employed canonical discriminant analysis to describe the observations in terms of linear combinations of the original variables. Our intent was to be able to visually observe whether the clustering procedures yielded a true separation between groups. We produced a graphic representation of the groups by plotting the first two canonical variables which were linear combinations of the original variables, using cluster number as the symbol (see Figure VI, Figure VII and Figure VIII). At first glance, the plots are

indistinguishable, each looks identical except for the symbol designation of cluster number (note: Cluster 1 is replaced with the letter A and Cluster 10 is replaced with the letter J). The graphs provide evidence for the existence of three non-overlapping groups.

We have included plots of the Cubic Clustering Criterion, Pseudo F and T^2 statistics vs. the number of clusters for Ward's method. The plot of the Cubic Clustering Criterion (CCC) against against the number of clusters suggests a peak at a value of 10 distinct clusters. The plots of the pseudo F statistic and T^2 statistic against the number of clusters indicates a peak value at 2 or 3 clusters. These graphs are displayed in Figure IX and Figure X.

We have also included a cluster summary report for the density linkage method in Table VI. The results of the density linkage method indicated the existence of three modal clusters. A tree diagram displaying the results of hierarchical clustering as a tree structure is included for this method in Figure XI. The tree diagram also suggests a division into three different groups.

Summary statistics for each cluster defined by the density linkage method depicting differences in average CPU, IOCOUNTs, number of data base calls (RT1DBDBC), the amount of storage used from the storage pool (RT1DCSUP), the number of records current for the run-unit (RT1DCCUR), the number of program calls (RT1DCNPC), the number of program loads (RT1DCNPL) and average response time (elapsed time) are included in Table VII. The plot of the first two canonical variables indicates that clusters 21 and 9 are different from the other groups. The cluster means presented in in Table VII indiate that cluster 9's usage of resources is below the average and that most of the performance measures for cluster 21 are also below the average (with the exception of the number of data base calls and CPUtime which are slightly above the average).

During the presentation we will review the clusters and discuss their interpretation in terms of business groupings, types of work processed and resource usage.

Case Study Summary

The results of the various cluster procedures indicate that at least 3 clusters should be formed from the bulk of the data. The Cubic Clustering Coefficient produced for WARD's method peaked at nine to ten clusters. However, even using WARD's method, the plots of the first two canonical variables suggested that only three of the groups were non-overlapping and of any real significance. It is not unusual for the cluster procedures to produce different results nor is it unusual for them to produce groups which are truly disjoint. In many cases the clusters produced will not be separated by a great enough distance and it may be necessary to merge nearby clusters by hand to obtain a satisfactory partition. The question then arises, How do you know when you have a good set of clusters? We have suggested the usage of some graphic methods to aid in determining the optimal number, including the plot of the CCC against the number of groups and graphs of the canonical variables. The density linkage clustering methods will provide an indication of the number of modal clusters produced. During the presentation we will discuss this problem in greater detail.

It is important to consider cluster analysis as part of a set of techniques for use in exploratory data analysis. The value of using cluster analysis is that it may suggest relationships between new combinations of variables and observations that had been previously unnoticed. It must be an iterative process. One has to decide on the choice and number of variables to include as input to the clustering algorithm and one has to examine the validity of the clusters in terms of some outside set of criteria and their interpretive value.

The ultimate criterion for evaluating the clusters is whether these groupings facilitate the achievement of the analysts study objectives. The groups formed after careful systematic analysis should be meaningful to the investigator. For example, can the clusters be defined in terms of groups of transactions which perform similar functions (Update transactions vs. Inquiry), or in terms of groups of transactions which comprise a business function (accounts payable, receivable etc.). During the presentation, I will review some of the criteria and also discuss the "meaning" of the groups formed.

Conclusion

The workload characterization process provides a definition of the business workloads, their usage of data processing resources and service requirements. The process can help us to identify long-running, resource intensive transactions, to determine whether guaranteeing an average on-line host response time less than 1 second is feasible and it helps us to discover that not all of the transactions in the system are similar in terms of the amount of resources they consume. By profiling transactions based on resource utilization parameters and forming homogeneous workloads, we can produce more meaningful performance reports and monitor resource usage more effectively. In addition, using homogeneous workloads as input to both analytic and statistical forecasting models will ensure more accurate predictions of future system behavior.

Our objective in this paper was to describe a general methodology for workload characterization for subsystems, to discuss some of the details involved in performing the analyses, and to apply these techniques to characterize and develop an understanding of resource usage for IDMS systems.

While gaining an understanding of the system workloads, we should also gain better insights about what drives them and how they may change in the future. We can't expect to be able to determine how things will change in the future if we don't understand the present.

IDENTIFICATION OF TUNING OPPORTUNITIES THROUGH THE USE OF USER BEHAVIOR GRAPHS

Charles E. Hackett
The Guardian Life Insurance Company of America

ABSTRACT

The objective of this paper is to describe a terminal oriented perspective of analyzing on-line system performance. The information derived from this analysis can point the performance engineer toward previously unknown bottlenecks. Case studies are used to examine the analysis technique. The data used is drawn from Landmark's CICS Monitor detail file, and is transformed in custom BAL programs. SAS procedures are used to report the information, which is then used to chart User Behavior Graphs.

I. INTRODUCTION

The need to identify critical CICS transactions can be satisfied by simple criterial. This includes selection by: executed most often, longest response time, resource contention, or loudest complaints. However, are these all the transactions that affect the users service, and in the proper context?

To assess this, we need to view the CICS workload from a terminal user's perspective. User Behavior Graphs (UBG) describe the interaction of the CICS terminal users in a graphical model. The UBG can identify all the transactions related to a business function, uncovering bottlenecks in the users' path through the system. The UBG more accurately describes the workload than a list of transactions. Tuning the UBG will more directly benefit the CICS users than tuning random transactions.

II. THE APPROACH

The CICS systems used in a production environment are very complex. They contain multiple application systems, scores of transactions, hundreds of terminals, and many User Behavior Graphs.

In a paper written by Calzarossa and Trivedi (CMG '86), UBGs are used to build a model for workload characterization and resource utilization. In that paper, each user is represented by their own UBG. In approaching the voluminous data of the production system, to treat user individually becomes impractical. In fact, the Calzarossa and Trivedi solution to this obstacle was to define all the users to be statistically identical when solving their model.

Each CICS system is not a single, massive User Behavior Graph. Under the hood of each CICS system we find multiple UBGs. It is an important distinction to note that a user may operate according to different UBGs at different times, and that the bridge between UBGs must be identified as such. This separation will help in defining the UBG structures of the system.

It follows then that the UBGs to study are those UBGs commonly used within the set of all UBGs.

What does a UBG look like? Calzarossa and Trivedi define the UBGs: each node represents a transaction, each line a probability of transition to another node, and a sojourn time that represents the sum of data entry time, response time, and user think time. The sojourn time is associated with a visit at a node.

Note: reading the Calzarossa and Trivedi paper will give the reader a modeling perspective on this topic, as well as explain in detail their definitions. The method of UBG construction described in sections III and IV of this paper was used for developing UBG charts from actual production system data.

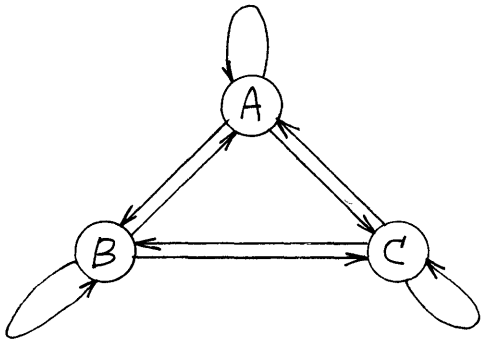

Figure 1 - UBG diagram.

Using a CICS monitor to extract detailed data, the transactions run time and start time are selected. From this data, we can calculate the idle time between successive transactions executed for a terminal using custom BAL programs. Thus, in this papers' representation of the UBGs, the transition has a time associated with it, the idle time. To use the Calzarossa and Trivedi model definition, the run time plus the idle time can be equated to the sojourn time (the time associated with the users visit at the node). It should be noted that the run time does not equal response time. The idle time calculated from the Landmark Monitor's data contains components that should be attributed to response time, such as: MVS, VTAM, CICS overhead and network transmission. When reviewing the Monitor's data, this should be kept in mind.

The limitations of using only a CICS monitor as the source of data prevent a better analysis of the terminal users perspective of the CICS system (ie, we don't have true response time). However, we can build the UBG structures. To do so. we need to transform the detail file into a set of transaction sequence records using the custom BAL programs. Standard SAS procedures are then used to summarize the transaction sequences.

III. TRANSACTION SEQUENCE

A single transaction sequence is composed of two successive transactions executed for a unique terminal. The level of detail needed to generate UBGs does not require anything other than the primary and secondary transaction names of the sequence. Any data associated with the sequence can be carried, and for the UBGs used in this paper the transactions' run times, the idle time between the transactions, and the start time of the first transaction, which is the start time of the sequence, are reported.

The UBG in figure 1 is composed of nine transaction sequences. The probability of transition from each node can be calculated from the nodes' transaction sequences

in which it is the primary transaction. The percentage of the whole UBG that each sequence represents can be calculated. This percentage (the weight) will identify which paths are heavily traveled relative to the UBG.

To develop the global set of all transaction sequences for the CICS system, the detail file must be sequenced by terminal id and transaction start time. The data is then combined into transaction sequence records. The fields selected from each detail record are:

* TATRANS - transaction name
  TASYSID - system identifier
  TADATE - date
  TATERM - terminal identifier
  TASTIME - transaction start time
  TAPTIME - transaction stop time

* Landmark's Monitor field names and definitions.

Other data that are applicable to model construction could be stripped off as well. However, for the UBGs constructed in this paper these data are not needed. (In fact, to build the most skeletal UBG, the primary and secondary transaction names are all that are required.) To demonstrate the analysis technique, some descriptive data are carried. The transaction sequence records in the case studies are composed of the terminal id, sequence start time, primary transaction name and its run time, the secondary transaction name and its run time, and the idle time between the primary and secondary transactions.

To demonstrate the content of a UBG; terminal X executes transaction A, B and C in that order. The transaction sequence records produced are:

Term=X,Primary tran=A,Secondary tran=B
Term=X,Primary tran=B,Secondary tran=C

If no other transactions are executed by X, then the UBG for the user at terminal X is:

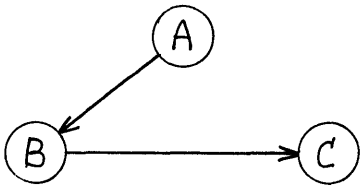

Figure 2 - UBG for X.

In the example UBG in figure 1, there are only three transactions, yet there are nine transaction sequences. If each transaction of a production CICS system could transition to all other transactions, as figure 1 demonstrates, UBG construction would crumble under the weight of computational requirements. In observed systems the actual number of transitions are significantly less. They do not increase geometrically with respect to the number of transactions.

The summarization of the whole set of transaction sequences will give us the components of the CICS systems' UBGs. In the case study appendage, figure 1 shows a transaction summary, and figure 2 is a list of the summarized transaction sequences. Though not an end in themselves, the sequences are informative in that they do demonstrate the interrelationships of the transactions. The UBGs to be constructed will use these transaction sequences as input.

IV. UBG CONSTRUCTION

UBGs are built from two types of transaction sequences. The first is a unary sequence, in which the users' transition is to the same transaction. The second is a binary sequence, in which the user transits to a different transaction.

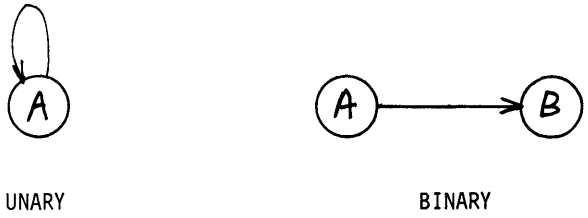

Figure 3 - Sequence types.

UBGs are built from some combination of these two transaction sequence types. The UBGs that are then constructed tend to be of four basic flavors; unary, serial menu, or matrix. In practice, UBGs are combinations of these four.

.Unary: the UBG is composed of a unary transaction sequence only.

Figure 4 - UNARY

.Serial: the transitions tend to flow in a sequential manner through the UBG.

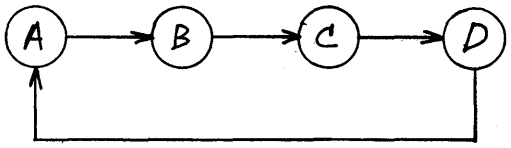

Figure 5 - SERIAL

.Menu: a menu transaction dominates a UBG through which all transitions either enter of leave.

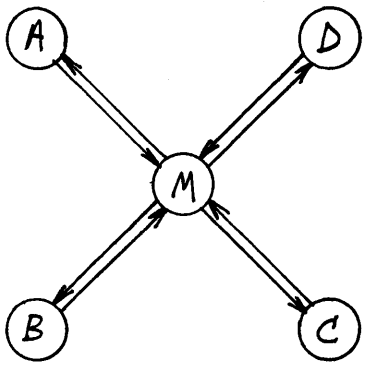

Figure 6 - MENU

.Matrix: each transaction in the UBG can transit to all the other transactions.

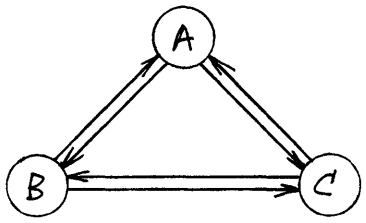

Figure 7 - MATRIX.

.Complex: combinations of the four basic UBG flavors.

When completed, a UBG will describe the interraction amongst the transactions in both diagram and tabular form. (See figures 3 through 7 in the appendage for the case study UBGs.)

We must first select the content of the UBG we are to build. By choosing a "big hitter" transaction as a start, (a big hitter being a major transaction in the system, whether it be selected by: executed most often or longest run time or some other criteria), we can see which UBG it belongs to, and the affect of that transaction on the UBG. Note that a transaction can appear in one UBG only. The sequences associated with the targeted transaction are selected for inclusion in the UBG. The directly related transactions (those that the initial transaction transited to) are then selected. In turn, these transactions are used to select their transaction sequences. This method will select all related transactions, no matter how indirect, including the between-UBG bridge sequences. The tree will continue to grow until we halt selection by some arbitrary condition. The technique best suited to limit the selection process is a transaction naming convention. (For those unlucky souls who have no naming conventions, the transaction selection can be made though table lookups. However, this may require pre-determining the correct transaction mix.) An example will best illustrate this efficient method.

> From the appendage figure 1, we select the transaction executed most on the system, GBLB. What is the context of its use? In the transaction sequence list (figure 2), the GBLB sequences are selected. Then the transactions that GBLB transits to and from are selected and their transaction sequences follow. This will continue indefinitely, so it is here we must limit the iteration of the selection process. Those sequences that include a non-GBLx transaction are presumed to be a bridge to or from another UBG. Hence, we can select the content of the UBG to be only GBLx to GBLx transaction sequences.

Once the appropriate transaction sequences have been selected, to draw the UBG becomes an exercise in connect the dots (er, nodes), using the sequences to direct our connections. The sequences are entered into a table which is then used to calculate the transition probabilities and the weight. The weights are then carried back to the drawing, and marked next to the appropriate transition line. The construction of a single UBG is thus completed, and it is an isolated UBG from the other UBGs in the system.

V. UBG ANALYSIS

GBLx UBG

In figure 3 of the appendage, the GBLx UBG is shown. The table associated with the graph contains the transaction sequences of the UBG. The sequences' count of occurences, the probability of transition from the primary transaction, and the percentage of the whole UBG that the sequence represents are shown.

What does the UBG tell us that the transaction summary list doesn't? We could have guessed that the GBLx transactions were interrelated, but not how, and not with the proper weights given to the paths. Some observations we can make of the GBLx UBG:

- .it is matrix oriented
- .the B to C to B path is most heavily traveled
- .the B to E to B path is second most active
- .the unary activity centered on F and E shows that once arriving at those nodes, the users tend to execute the transaction repeatedly (called an extended visit)
- .the A to B activity is heavier than B to A, possibly reflecting that A is the users' entry into the UBG, and that bridges to other UBGs occur from the other nodes.

Researching further using a batch analysis report shows that transaction B and F share a file. During B's execution, a keyed search is made of the file, and if a browse is needed to locate the correct record, the F transaction is used. Performance gains to this file will improve the run times of B and F. The reduction of this run time and the corresponding response times will enable the users to cycle through the UBG at a faster pace. Assuming a backlogged workload, ie latent demand, we could expect the arrival rate of all the transactions of the UBG to increase. This is easily obtained analytical information that, without the UBG, would have necessitated time consuming effort.

GPSx UBG

Figure 4 of the appendage is the GPSx UBG. Three of the ten most heavily executed transactions (as shown in the transaction summary, figure 1) are in the GPSx UBG. This UBG demonstrates a combination of a menu UBG centered on the A transaction, with heavily used unary sequences at nodes D,C, and T.

How does this differ from the GBLx UBG shown in figure 3 of the appendage? Because of the central nature of A, improvements (or degradation) to transaction A will directly affect the pace of the entire UBG. Changes to the unary oriented transactions will affect the others of the UBG, but not as significantly as the A transaction. However, this is not to say the unary-oriented transactions are less significant in the users perception of performance. Because of those transactions' relative high activity, the D, C and F transactions are significant components of the UBG.

NCxx UBG

Figure 5 of the appendage is the NCxx UBG. It is a menu UBG, centered on the unary sequence O2. Half of all activity in this UBG occurs in the central unary sequence. The many other transaction sequences included in this UBG sum to the remainder, yet individually are insignificant in comparison to the O2 unary sequence. The O2 transaction is involved in 97% of the UBG sequences as either the primary or secondary transaction. The key to users following this UBG is the central transaction.

NAxx UBG

Figure 6 of the appendage is the NAxx UBG. This is a unary UBG, with only the NA77 unary transaction sequence as a component. Users who follow this UBG are affected by the performance of the NA77 transaction only.

GLxx UBG

Figure 7 of the appendage is the GLxx UBG. This is a complex UBG. The 02 transaction acts as a menu to serial legs emanating from it. At the ends of the serial legs are matrix-type structures. Unary sequences occur along the serial and matrix sections, the end result being the complex GLxx UBG.

In analyzing a complex UBG, it is appropriate to split the UBG into sub-UBGs. The 02 transaction can be viewed as the center of a menu UBG, with the 30's, the 20's and the 10's serial UBGs emanating from it. The 32 transaction is heavily used, and is part of a matrix UBG in conjunction with the 34 and 35 transactions. The 32 unary sequence has a large UBG weight, and could be viewed as a unary UBG. The 02 and 32 transactions are end nodes of a serial UBG passing through the 30 and 31 transactions. The serial UBG operates in both directions along the path.

Because of the high activity associated with the 02 and 32 transactions, the serial UBG from 02 to 32 is of secondary importance only to the 32 unary sequence, and the 02 menu sequences.

What does this UBG tell us about the GLxx transactions? The 02 and 32 transactions are important in their own right, and are the keys to the whole UBG. The performance of these two transactions affect the performance of most users of this UBG.

The execution of the UBG occurs in a very structured manner. Path selection restrictions imposed on the users serve to simplify the application to users of the underlying database. If the structure is in place for this reason alone, and not for processing requirements, then expert users (as opposed to novices) will be impeded by this path structure, for they must pass through the intermediary transactions enroute to the desired node. This may or may not be the intention of the design.

VI. CONCLUSION

The construction and analysis of User Behavior Graphs clear the view for the performance analyst. By placing the transactions within the context of their use, we can identify critical paths in the system. In the future, development of software that will do controlled generation UBG models will enable capacity and performance studies of the CICS workload more directly based on the terminal users interaction with the CICS system.

VII. ACKNOWLEDGMENTS

Thanks to Ted Osmer, Melvin Swanson, and Bill Yarnall for their constructive editing and advice, and most especially to Ted for his encouragement.

VSAM SPECIFICATION AND TUNING:
OPTIMIZATION OF VSAM PERFORMANCE IN BATCH AND CICS ENVIRONMENTS

Frank Bereznay
Automobile Club of Southern California

ABSTRACT

Proper specification of a VSAM data set can have a major impact on the amount of DASD space needed to store the data and the resources required to process it. This paper summarizes experiences gained from VSAM tuning efforts. The paper begins with an overview of the structure of a VSAM Key Sequenced Data Set (KSDS) and a discussion of 3380 DASD architecture as it relates to track utilization percentages for the various control interval sizes. A DEFINE CLUSTER statement will then be used to review specification options and examine the interdependence between the size of the data control interval, index control interval, control area and the length of the retrieval key. Buffer management follows, showing how proper buffer specification can reduce the number of data transfers needed to process a record. This section includes techniques on how to calculate the number of index buffers in a VSAM data set and how locally shared resource (LSR) pools function. The final topic of the paper addresses update processing which includes an explanation of the potential overhead associated with it and how freespace can be included in the data set to reduce or eliminate this overhead.

INTRODUCTION

VSAM, the virtual storage access method, is widely used in system and application areas and yet, despite this widespread usage, there tends to be a lack of understanding of how these data sets should be specified and tuned. It has been observed that a common technique to specify a VSAM data set is to locate a DEFINE CLUSTER statement that exists for some other data set and then change the minimum number of parameters needed to make it work for the new data set. While this technique typically generates a return code of zero from IDCAMS, the data set produced may not be what is really wanted or needed. The VSAM specification/tuning task is even more critical in a CICS environment where many (frequently over 100) data sets are allocated and items such as buffer sharing and string numbers can have a major impact on response time and resource usage.

This paper summarizes the experiences gained during VSAM tuning projects. It will identify key specification areas and how these items can have a significant effect of the amount of DASD space required to store the data and resources required to process a record. In an online environment, attention to these details can translate into a dramatic reduction in response time. In batch environments it can represent major reductions in run times. In both environments proper specification and tuning can reduce the resources required to process records.

OVERVIEW

A KSDS (Key Sequenced Data Set) is a type of VSAM data set that supports sequential and direct processing. When direct processing is performed records are retrieved and written based upon the value of a key field that is part of the data record. Sequential processing is performed by retrieving or writing records in ascending sequence based upon the value of the key field.

There are three catalog entries associated with a VSAM KSDS data set. These entries are; (1) cluster entry, (2) data component entry, and (3) index component entry. The cluster entry contains the name used to reference the data set and establishes the connection or association between the cluster name and the two component names which make up the data set. The data component entry locates the part of the data set that contains the user data. The index component, which actually consists of two parts, is a collection of retrieval keys and pointers which are used to allow keyed retrieval, updating, and insertion of records within the data set. It is organized in a hierarchical manner, normally with three levels. The bottom level of the index component is called the sequence set and all upper levels are collectively called the index set.

The control interval represents the amount of data that is transferred to and/or from disk as part of an I/O operation. It is NOT necessarily the physical block size for the data set. In many cases the actual physical record size is smaller than the control interval specified. The control interval can also be thought ot as a collection of records that are pointed to by an entry in a sequence set record of the index component.

A control area is a collection of control intervals, usually a cylinders worth. There is a one-to-one relationship between the number of control areas in a VSAM KSDS and the number of sequence set records in the index component. This one-to-one relationship implies that a sequence set record must be large enough to hold a high key entry for each control interval in the control area. If you assume a 4K data control interval size and a full cylinder control area there will be 150 control intervals in the control area (on a 3380 device). The sequence set record in this case must be large enough to store a key value and pointer for each of the 150 control intervals within the control area.

The retrieval key, interestingly enough, is key to the proper specification of a VSAM KSDS data set. This is the character string used to locate records for direct processing. VSAM is very sensitive to the size and compressability of these keys since they must be stored in the index component. It follows that the length of the retrieval key is a factor to be considered when choosing the control interval size for the index component and the size of the control area for the data component.

3380 OVERVIEW

The 3380 DASD device is not a byte addressable storage medium, data is stored in multiples of 32 bytes plus some overhead for system usage. For VSAM data sets this implies that the percentage of the track that is used for data will differ based upon the size of the control interval that is chosen. This difference can be quite significant with the track utilization percentage ranging from 50% to 85% of total track capacity. Figure 01 is a chart of control interval sizes and the amount of data they store on a track under DFP version 1. Track utilization data will change with DFP version

2 because physical record sizes will match the control interval size.

Choosing the proper control interval size depends upon the intended use of the data set. When it is used in batch applications the only consideration is storage efficiency. However, when the data set is used in a CICS environment the control interval size establishes what buffer pools will be used for the data set. Unless the data set is exceptionally large, control interval sizes should be standardized to improve CICS buffer management. They should also be kept on the smaller side to minimize data transfer time and buffer usage for direct processing.

As a general set of guidelines, the following control interval sizes should be used for VSAM KSDS's in a CICS environment for small to medium sized (less than 2K) logical records. The 80/20 rule applies here. These CI sizes should be used for the 80 percent of the data sets that represent 20 percent of the storage allocated. In most cases the better track utilization of the data CI size will outweigh a poor fit based upon logical record length. The other factor to consider is the length of the retrieval key which will be discussed later.

Primary Access Method	Data CI Size	Index CI Size
Direct	4096	2048
Sequential	8192	1024

22528	24	540,672	88
26624	20	532,480	87
28672	21	602,112	98
30720	18	552,960	90
32768	18	589,824	96

NOTE: These track utilization calculations are for a DFP version 1 environment.

The track utilization percentages are based upon 614,400 bytes which is the maximum amount of user data that can be stored on a track.

SPECIFICATION

A DEFINE CLUSTER statement is prepared and executed by IDCAMS to allocate a VSAM data set. The following is an example of a DEFINE CLUSTER statement for a KSDS:

```
DEFINE CLUSTER (NAME(POOR.EXAMPLE.KSDS)          -
                FREESPACE (0 10)                 -
                IMBED                            -
                KEYS(0 12)                       -
                RECORDSIZE(225 225)              -
                SHAREOPTIONS(2 3)                -
                VOLUME(PON832))                  -
          DATA (NAME(POOR.EXAMPLE.KSDS.DATA)     -
                CONTROLINTERVALSIZE(4096)        -
                CYLINDERS(30 5))                 -
         INDEX (NAME(POOR.EXAMPLE.KSDS.INDEX)    -
                CONTROLINTERVALSIZE(512)         -
                TRACK(1 1))
```

VSAM specification options that can affect performance, and are independent of the physical characteristics of the data set, include selection of control interval size, sizing of the control area and use of IMBED to reduce seek activity.

SIZING THE CONTROL AREA

Large retrieval keys can waste tremendous amounts of disk space unless control interval sizes and possible control area sizes are adjusted to accommodate for the large key. This is a passive specification problem because no error or warning message is issued when a control area is partially loaded because a sequence set record filled up.

The control area is a collection of control intervals. The size is usually one cylinder, however it can be as small as one track. Each control area is assigned one sequence set record to hold a compressed high retrieval key for each control interval in the control area. If the retrieval key is large, or it does not compress, the sequence set record will fill up before the control area is loaded. When this occurs the loading of that control area is stopped and VSAM moves on to the next control area to continue the loading of the data set. The remainder of the first control area is now dead space or unusable.

The following factors should be considered when reviewing a control area specification:

- Size of the control area - This is determined by the space allocation values for the data component. It is the smaller of the primary allocation, secondary allocation and one cylinder.
- Data control interval size - This determines the number of control intervals within the control area.
- Index control interval size - This determines the size of the sequence set record.
- Length and compressability of retrieval key - The size of the compressed retrieval key times the number of control intervals in the control area plus some control fields determines how big the sequence set record must be to fully use the control area.

Using the above DEFINE CLUSTER as an example we find that:

- The control area is one cylinder. This is the value used since the primary and secondary

allocations are greater than one cylinder. In order to define sub cylinder control areas the space allocation for the cluster must be in tracks with either the primary or secondary allocation being the desired control area size.

- There are 140 control intervals in the control area. A 4096 size results in 10 control intervals per track. Since IMBED is chosen there will be 14 tracks of data, (the 15th track is used to store a replicated sequence set record) which accounts for the 140 control intervals.

- The sequence set record is 512 bytes in length. The IMBED option DOES NOT increase the size of the sequence set record. It causes the 512 byte record to be repeated as often as possible on a single track.

- The retrieval key is 12 bytes in length. It is very difficult to determine the compressability of a retrieval key without studying the data itself. Generally speaking larger keys compress better than smaller keys and old data sets have keys that compress better than new data sets. The standard assumption is a 50% compression factor.

The following is a formula to aid in calculating the capacity of a sequence set record assuming a 50% compression of the retrieval key.

```
# of Entries = (CI SIZE - 31)/((Key Length/2) + 5)
             # of Entries = 43.7
```

In this example the sequence record would fill up after about 43 to 44 entries (or control intervals). Since the control area contains 140 control intervals the remaining 95 to 96 would be unusable. Roughly 68% of the cylinder would be wasted.

If the index control interval size were increased to 2048 the capacity of the sequence set record would be about 183 entries. This would allow the sequence set record to support a full control area's worth of control intervals before filling up.

If the index control interval size could not be increased then the control area should be made sub-cylinder to allow for full cylinder utilization. This would be done by making the space allocation in tracks and making the secondary allocation 4 tracks. When allocating sub-cylinder control areas and IMBED is used, the allocation must not include the track used for the imbedded sequence set record. In this example the 4 track control area would be combined with one track for the sequence set record making the total control area 5 tracks. This would divide evenly into the 15 tracks of a cylinder allowing 3 control areas per cylinder.

MISCELLANEOUS SPECIFICATION NOTES

The IMBED option causes the first track of a control area to be used to store the sequence set record assigned to that control area. The sequence set record is replicated around the track to minimize rotational delay. By placing the sequence set record and data on the same cylinder a single seek will normally satisfy both record retrievals. Using the IMBED option with a full cylinder control area will reduce the data storage by 1/15 or roughly 7%. This figure will be higher for sub-cylinder control areas.

This option is recommended because it can improve performance and because it reduces the number of control intervals in a full cylinder control area. Assuming a 4K data control interval on a 3380 device a full cylinder control area consists of 150 control intervals. If IMBED is specified the number is reduced to 140. Reducing the control area by 10 control intervals is not a major reduction but it can help keep a sequence set record from filling up.

Keep data and index components on the same volume. It can be argued that splitting the components reduces head contention and this can be true. However, a better solution is to keep the index set resident in memory and use IMBED to allow a single seek to serve two purposes. Splitting the components increases the complexity of data recovery in the event a volume fails. A full volume restore of half a VSAM KSDS may render the entire data set useless.

CONTROL AREA SIZING EXAMPLE

A set of VSAM specification standards were developed for a CICS environment where VSCR (Virtual Storage Constraint Relief) was a concern. The standards included a 2K data control interval size and a 1K index control interval size with IMBED as the default. Around 225 data sets were defined using these standards and they occupied 7 single density 3380 disk volumes. The 2K/1K control interval sizes would require sub-cylinder control areas for retrieval keys as small as 2 bytes. The average retrieval key length for these data sets was over 20 bytes and full cylinder control areas were used.

The problem was initially identified by the DASD management group, when they compared the user data being backed up to the amount of disk space allocated to the DASD pool. The VSAM data sets represented 1.1 giga-bytes of user data and 3.1 giga-bytes of DASD was being allocated to it. This led to the development of a storage efficiency ratio; user data divided by storage allocated.

The initial efficiency ratio for these VSAM data sets was 31%. For every 100 cylinders allocated only 31 contained user data. The remainder were used for system overhead purposes or dead space. During the next three months these VSAM data sets were respecified using sub-cylinder control areas, typically 3 or 5 tracks. At the end of the project the storage efficiency ratio increased to 49%. This represents a 58% increase in track utilization or a reduction of over 2 disk volumes with no reduction in user data.

Some additional work went into analyzing the storage efficiency ratio. While 49% was better than 31% it still seemed pretty low. Under ideal conditions the ratio could get into the mid 70%'s. This required a perfect fit of the logical record in the control interval and no specification of freespace in the data set for update purposes. For data sets that were updated the best storage efficiency ratio was in the low 60%'s. After the sizing issue was corrected, logical record fit and freespace specification tended to have the greatest impact on the storage efficiency ratio.

BUFFER MANAGEMENT

The objective of buffer management is to keep frequently referenced records in memory to improve response time for direct processing and reduce resource consumption. If minimum buffering is used, the average VSAM data set will require four data transfers to retrieve a record. There will be a separate record retrieval for each level in the index component and one record retrieval for the data control interval.

Buffers can be allocated to keep the index set, usually 4 to 10 records, memory resident. This can cut the time for the I/O process in half. Furthermore, the processor time associated with performing the I/O is eliminated. In this situation you can improve response time and at the same time reduce CPU usage by using a small amount of virtual and real storage.

CALCULATING THE SIZE OF THE INDEX SET

The index component consists of fixed length records, with the record length being the control interval size. The easiest way to calculate the number of records in this component is to divide the high used RBA (Relative Byte Address) by the control interval size. The record count field in the LISTCAT listing may not be accurate. Depending upon how the cluster was defined, some additional calculations may be needed to determine the size of the index set.

1) IMBED and NOREPLICATE - Take the high used RBA for the X'00' extent type of the index component and divide it by the index control interval size. This should divide evenly and represent the number of records in the index set. When IMBED is specified the sequence set records are physically located with the data and are not part of the X'00' allocation.

2) IMBED and REPLICATE - Take the high used RBA for the X'00' extent type of the index component and divide it by the index control interval size. VSAM adjusts the RBA address to compensate for the record replication. This should divide evenly and represent the number of records in the index set.

3) NOIMBED and NOREPLICATE - The X'00' extent will contain sequence set records in the allocation so they must be removed from the calculation. To do this you must take the high used RBA for the data component and divide it by the control interval size and then by the number of control intervals in a control area. This result is the number of active control areas in the data set, i.e. the number of sequence set records. Then calculate the index set as in example #1 and subtract the number of sequence set records from it. The result is the number of records in the index set.

4) NOIMBED and REPLICATE - Similar to number 3 the index allocation contains sequence set records. Calculate the number of active control areas as in number 3. Then calculate the size of the index component as in number 2. Finally subtract the number of active control areas from the size of the index component and the result is the size of the index set.

CALCULATING BUFFER REQUIREMENTS FOR BATCH PROCESSING

The index buffer allocation for direct access batch processing will be the size of the index set plus 2 (one for the sequence set record and one to cover a CA split). The data buffer allocation should be 2 (one for data and one for CA split). When allocating buffers for sequential processing allocate two index biggers and approximately 14 data buffers. It is recommended that these buffer specification be made in the JCL, not as part of the definition of the data set or as part of the open.

CALCULATING BUFFER REQUIREMENTS FOR CICS PROCESSING

The CICS environment provides two techniques for VSAM buffer management: (1) non-shared buffer allocation and (2) locally shared buffer pools. The non-shared technique established a separate set of file buffers for each data set and the shared technique allows a group of data sets to use a common pool of buffers. There are advantages and disadvantages to each technique but generally share buffer pools are recommended if possible.

CICS allows multiple tasks to concurrently access a single data set. This multi-tasking process places some additional demands on the size of the buffer pool. Typically you will need one additional index record for each concurrent user. The parameter that control the number of concurrent users is called the string number (STRNO) and is specified in the FCT for the data set.

NON-SHARED RESOURCE (NSR) BUFFER POOLS. For direct processing use the size of the index set plus 1 (CA split) plus the string number. If the string number is 5 it implies 5 users may concurrently process the data set and each user may come up with a unique sequence set record. To keep these sequence records from overlaying the index set, the buffer number is increased accordingly. These values will be placed in the CICS FCT table entry for the data set.

LOCALLY SHARED RESOURCE (LSR) POOLS. As the name implies this technique uses a common set of buffer pools for multiple data sets. As a default, the size of the pool is determined by the index and data buffer specifications for the data sets that are assigned to it. CICS will sum the values and create buffer pools 1/2 the number summed. The size of the buffer pools can be further adjusted with a macro at the end the FCT table.

Shared buffer pools have two main advantages: (1) they use less virtual and real storage because multiple data sets share the same buffer pools, and (2) it is possible to read all records associated with a record request from in memory buffers. When using non shared buffer management only the index set will be read from in memory buffers. With shared buffer pools the entire index component and the data control interval will be read from in memory buffers if present.

When data sets are assigned to an LSR buffer pool the index and data buffer specifications will not limit the number of buffers the data set may use. As many buffers as needed will be allocated from the pool. The retention of these buffers in memory will be determined by the size of the pool and the frequency of reference of the records. However, VSAM will recognize the string number specified to limit the number of concurrent users of the data set. This allows the string number parameter to be used as a limiting factor to keep a high use data set from overwhelming a buffer pool.

The buffer pools are managed on a least recently used (LRU) basis. When the buffer pool fills up the record that hasn't been referenced for the longest time will be purged. To evaluate the success of a buffer pool a hit ratio is used. This is the ratio of records read out of memory divided by total record requests. For index buffer pools this percentage should be in the high 80's to low 90's. Data buffers are normally in the high 40's to mid 60's. CICS shutdown statistics can be used to develop this ratio.

The size of the buffer pools should be adjusted until the proper hit ratios are achieved. Making the pools excessively large will drive up processor utilization

because the pools are frequently serially scanned. If they are left too small there will be little or no successful look aside processing and transactions may be delayed waiting for buffer availability.

When data sets use this buffer technique it is very important to use different control interval sizes for data and index components. Records are assigned to buffer pools based upon the control interval size, not their use. Data and index records will end up in the same buffer pool if they have a common control interval size. In this situation the data buffers will tend to crowd out the index records because of their greater number.

CICS BUFFER MANAGEMENT EXAMPLE

An application owning region in a CICS MRO complex was experiencing frequent program compressions (greater than two a minute), which was assumed to the source of poor service. To eliminate this problem the MRO complex was expanded and half of the workload was moved into a separate region. After the change was implemented program compressions were reduced, however, response time improved only slightly averaging 3.5 seconds. The bottleneck became string waits on high usage VSAM data sets. A group of 5 VSAM data sets were getting between 2,000 and 3,000 string waits during a 10 hour day. OMEGAMON CICS showed that usage and queueing for these data sets was the major wait reason for the high response time.

These 5 VSAM data sets were reviewed and their entries in the FCT were changed to keep the entire index set memory resident and at the same time the string number was increased. It was calculated that the increased buffer specifications required 96K additional memory. This set of changes had a dramatic affect on all measures of the CICS workload.

The average response time dropped from 3.5 seconds to .5 seconds. At the same time the CPU usage of the region dropped from an average of 28 minutes per hour to 12 minutes per hour a reduction of 57%. Finally the transaction volume increased 13%, from an hourly average of 15,500 to 17,500.

The reduction in processing time was partially due to the fact that the total I/O volume for the region dropped 200K, from 1.4M to 1.2M. That can only partially account for the 57% reduction. We have concluded the remainder is the overhead associated with maintaining the transactions for it's active life. Before the changes, CICS had to manage the transaction for an average of 3.5 seconds and after the change it dropped to .5 seconds. During the life of the transaction it would be on the active and suspend chains and a set of control blocks and user data storage would be associated with it. Maintaining these resources for the extra time, 3 seconds, is assumed to account for the CPU usage that was recovered by reducing the response time.

These improvements were achieved without using LSR buffer pools for the data sets. The use of the LSR buffer pools requires that a task cannot have multiple active I/O operations against a data set. The most common case of this is where a browse is started to locate a record and a get for update is issued before the browse is ended. This programming technique will work in a NSR environment but will create a "deadly embrace" in a LSR environment. The application logic needs to be checked and tested for this condition before LSR buffer pools can be used. A resource was not available to do this so the decision was made to stay with NSR buffer allocations for the high use data sets.

UPDATE PROCESSING

DEFINITION OF SPLIT PROCESSING

When records are added, and when they are updated if their record length increases, VSAM may be required to divide a control interval in half to provide space for the new or updated record. This is called split processing and it can occur at the control interval and control area level. The amount of split processing that will occur is determined by the pattern of update activity and the amount of freespace specified when the data set was defined.

Generally speaking, less is better when it comes to split processing. The main concern here is the overhead that VSAM incurs to perform the split processing. Control interval splits, dividing a single control interval, represent slight to moderate overhead. Control area splits, dividing an entire control area in half, represents significant to major overhead and should be kept to a minimum. Additionally, after a control area split, logically ascending data is no longer physically adjacent. This slows down sequential activity and tends to increase seek times for direct processing if it is clustered.

Assume that a VSAM KSDS was defined with no control interval or control area freespace. During the initial load VSAM will place as many records as possible in each control interval and use every control interval in a control area (assuming the sequence record is large enough). In this situation, the first record that is added to the data set will cause a control interval and a control area split.

A control area split will create a new control area and move 50% of the control intervals of the first control area into the new one. Assuming the 4K data control interval size and full cylinder control areas, this implies that 75 control intervals must be moved from one control area to another. During this process the index component is also modified to reflect the new location for the control intervals. Needless to say, this is a significant amount of data movement and can be the cause for delays in response time or batch throughput.

Once the control area split is completed, VSAM can continue with the control interval split by retrieving one of the empty control intervals and putting half of the original control interval in it to allow for the new record to be added.

FREESPACE SPECIFICATION

Freespace can be specified as a DEFINE CLUSTER option to provide pockets of empty space to allow updates to occur without having to do splits. It can be specified at the control interval and the control area level. Freespace is specified as a percentage and it represents the amount of space VSAM reserves during the initial load of the data set. Freespace percentages are not used during split processing, split processing always divides the control interval or control area in half. Specifying 25% control interval freespace with a 4K data control interval means 1K of the control interval is reserved. Making the same specification at the control area level implies that 38 of the 150 control intervals in the control area would be reserved.

The proper type of freespace, i.e. control interval or control area, depends upon the update patterns for the data set. If the update patterns are clustered then control area freespace is most effective. If the update activity is uniform across the entire data set then control interval freespace is a better choice.

With clustered update activity you let the first update split the control interval. Subsequent activity will be in the same area so there is a good probability that the original control interval, or the new one, will be used again. Remember that split processing always splits the control interval in half so there should be ample room for subsequent updates. In this case, specifying control area freespace keeps the control area splits from occurring.

When the update activity is uniform you assume any given control interval will only be updated once or twice. In this case you specify freespace at the control interval level and hopefully no split processing will occur.

Typically speaking, most update patterns seem to be clustered. Therefore, when you create a new KSDS that is to be updated, specify between 10% to 15% control area freespace and watch it for a couple of weeks or so to determine the update activity.

When KSDS consists of fixed length records, or if it consists of variable length records whose length does not change during update processing, you can use the IDCAMS listcat report to determine the pattern of update activity. Create the data set with only control area freespace and then compare the number of inserted records to the number of control interval splits. If the update activity is clustered you will get more inserted records than there are control interval splits. This implies that the split control intervals are being used for more than one record insertation. If, on the other hand, the number of inserted records is equal or close to the number or control interval splits you can assume the update patterns are uniform. In that case the control area freespace should be lowered and control interval freespace should be specified.

PRODUCTION ALLOCATION GUIDELINES

KSDS Definition

I. Standardize the control interval sizes
   - Direct processing 4K Data and 2K Index
   - Sequential processing 8K Data and 1K Index

II. Use full cylinder control areas
   - Review length of retrieval key

III. Use IMBED option

IV. Specifiy FREESPACE based upon type of activity
   - Control area for clustered update activity
   - Control interval for uniform update activity

Buffer Specification

I. Always keep index set memory resident

II. Use CICS LSR buffer pools whenever possible

IN PURSUIT OF DASD DATA PATH ALTERNATIVES

Ben Duhl
Storage Technology Corporation

ABSTRACT

Channel data transfer speeds and current data path connection architecture in the large IBM system environment may soon include faster transfer rates and additional pathing. This paper addresses the impact of these changes on subsystem performance via the use of simulation models and data processing workload profiles. Two key issues are presented: the impact of faster channels vs. conventional channels and enhanced subsystem porting architecture vs. current data pathing.

To attain knowledge learn things every day.
To attain wisdom remove things every day.
Lao-tse

BACKWARD

Is the adventure of improving DASD subsystem performance over? In the 1970s disk device service times saw reductions of 50% when the 3350 class DASDs were introduced. By 1980 the thin film head 3380 class DASDs boosted data transmission rates by a factor of 2.5 in addition to reducing mechanical seek times. The double capacity DASD devices came into service in 1985, retaining similar device service time characteristics, emphasizing the cost per megabyte and reduced floorspace requirements. In previous papers [1; 3] the performance issues of single capacity (1X) and double capacity (2X) device expectations were addressed. Highlights [1] included an expected reduction in maximum sustained throughput of about one-third with 2X devices configured for equal disk platter capacity as a 1X subsystem, and poorer IO response times with cached controllers servicing 2X configurations with unbalanced or skewed IO activity.

The recent introduction of yet faster mainframes from multiple vendors continues to emphasize the need for increasing parallelism in data processing activity, particularly for commercial as opposed to scientific applications. 3090 class mainframes increased the number of channels, for instance, from a maximum of 96 up to 128. Such hardware enhancements accommodate system parallelism growth requirements for online and interactive environments. But channel speed, for the time being, remains the same at 3 MB/sec. Speculation abounds about faster channel speeds for rotating DASD, either in native mode or only with cached controllers servicing IO previously staged into the controller memory. This paper addresses performance expectations and limitations associated with faster data paths and channels.

Increasing demand for current and new online software applications generally results in the need for more magnetic storage capacity. Enlarging disk spindle capacities has proven to be an economical alternative to acquiring more 1X spindles as part of the disk subsystem configuration. With increased data capacity residing on the same or lesser number of disk actuators, the challenge from a product performance viewpoint is to control IO wait times due to deferred requests caused by device busy or data path contention. Future disk subsystems will likely exploit faster data transfer speeds as well as more sophisticated alternate data paths between CPU mainframes and IO storage devices. Our intent is to evaluate such design options using a software performance model.

THE MODEL: ROUNDING UP THE USUAL SUSPECTS

To expand on a quote from Mark Twain, "rumors of the death of simulation models have been greatly exaggerated." Monte Carlo simulation models are very effective for evaluating new designs and functions on IO subsystems. A discrete event simulation model is structured in the IBM GPSS language [2] to reflect a variety of currently existing and hypothetically possible disk storage devices. The model permits us to represent not only the service time components of the rotating disk devices but also the various pathing components, including the control modules or heads of string, the directors, and the channels. We will vary key device characteristics as well as IO workloads which represent batch, online, and backup and restore operations. Additionally we will examine future designs as they relate to cached controllers and solid state disk devices.

A Monte Carlo design assures the stochastic effect on IO workload arrival rates, thus adding a measure of reality and a reflection of robustness to the observed performance results. Random number generators create peaks and valleys on IO requests which are independent of one another and conform to the Poisson distribution curve. In the open loop mode, we approximate the classical M/M/1 queueing environment for the IO devices while varying server characteristics in comparative simulation experiments. Dual ports (aka dynamic level selection, or DLS) and quad ports are more accurately represented as multiservers, perhaps M/M/2 or M/M/4, subject to constraints and connectivity with control modules and channels. Simulation models are especially well suited for representing current and future data path design alternatives without making progressively more complex mathematical assumptions a priori, as is the case with some analytical models.

In the closed loop mode, we are interested in capturing theoretical (and also unattainable) maximum sustained throughputs for a given disk subsystem configuration and a given IO workload. The closed loop mode uses a driver which creates IO arrival requests for each disk device address in the configuration. Upon successful completion of the IO request, the driver creates another IO request in the same clock unit. Such a driver will tend to saturate either the disk devices or the data paths, depending on the IO data transfer sizes and the actual subsystem configuration. We capture the maximum number of start subchannels (SIO) per second as well as subsystem effective data rate as seen on the channels.

MAXIMUM THROUGHPUTS WITH FASTER CHANNELS: THE ADVENTURE CONTINUES

In this study we configure 10 gigabyte disk configurations of 1X and 2X drives (Figure 1) and vary data transfer speeds from 3 Megabytes per second (MB/s) to 4.5, 6, and 10 MB/s. Such transfer speeds are

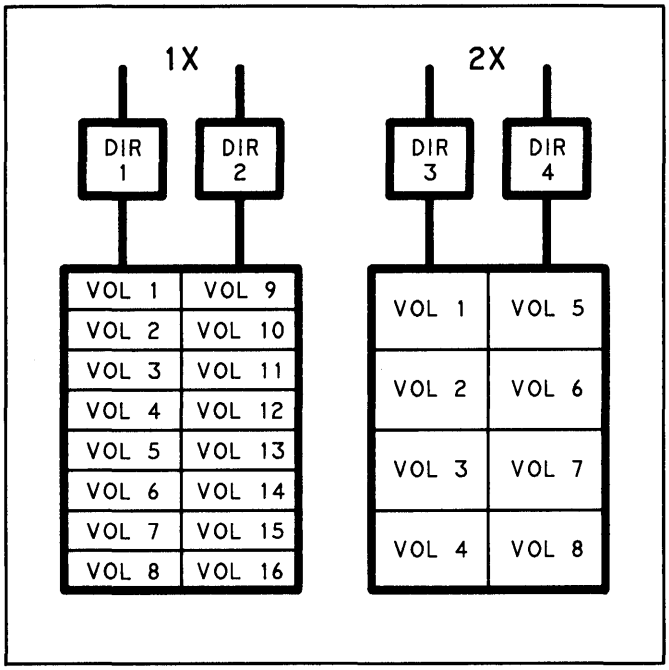

Figure 1. 10 GB DASD Configurations

considered to be valid design points in future disk products, likely with different form factors and not necessarily restricted to magnetic storage devices. Table 1 summarizes maximum throughputs across configurations using a pair of channels and a pair of directors. Note that the 1X disk configurations consist of four DASD storage boxes with a total of 16 actuators, and the 2X disk configurations consist of two DASD boxes with a total of 8 actuators.

Table 1. Maximum I/O Thruputs

2 x 16 1X Class

Transfer Speeds	4 KB Blocks At 50% Zero Seeks MB/s	Chans Busy	47 KB Blocks At 50% Zero Seeks MB/s	Chans Busy
3 MB/s	1.82	60.1%	5.19	94.1%
4.5	2.12	58.5%	6.65	83.4%
6	2.29	56.8%	8.23	80.3%
10	2.47	52.7%	11.58	74.5%

2 x 8 2X Class

Transfer Speeds	4 KB Blocks At 50% Zero Seeks MB/s	Chans Busy	47 KB Blocks At 50% Zero Seeks MB/s	Chans Busy
3 MB/s	1.37	45.5%	4.93	89.1%
4.5	1.44	39.8%	5.86	73.4%
6	1.49	36.9%	7.24	70.6%
10	1.56	33.3%	10.04	64.6%

Assumptions:
- Overhead I/O remains constant
- Closed loop mode
- Only data transfer portion allowed to vary

Data transfer sizes for all IOs are initially 4 KB and then 47 KB, the former representing nominal online and interactive IO and the latter representing large and possibly chained batch or perhaps disk to tape backup IO. The percentage of zero seeks in each simulation is statistically held at 50%. Sequentiality in disk IO patterns is a great influencer of zero seeks occurring with requests and results in increased data throughput. Looking at the cases in Table 1 we observe:

a) The 1X configurations always deliver more subsystem MB/s than do the 2X 10 Gigabyte configurations. This is because 16 read/write servers with 1X can do more work than 8 read/write servers with 2X configurations. In general the 1X configurations deliver 33% to 58% more data than the 2X boxes, as channel transfer speed is raised from 3 and up to 10 MB/s.

b) With 4 KB data transfer sizes, the overall improvements in throughputs are lower than what would be intuitively expected. This is because 4KB is a relatively small portion of a full disk track capacity, particularly with the faster assumed disk device transfer speeds. For instance a hypothetical DASD device capable of transmitting at 6 MB/s implies double linear track capacity (ie, 2 x 47.4 KBs, or 94.8 KB).

c) Protocol overhead accounts for over 50% of the channel utilization at conventional channel speeds of 3 MB/s; it takes 1.36 msec to transfer 4KB and an additional 1.4 msec for protocol overhead. More than one-half of channel and director connect time is consumed for non-overlapping protocol overhead.

d) Faster channels, then, reduce only the data transfer portion of channel busy conditions. Small data transfer sizes prevent significant improvements in IO response times.

e) With online and database applications representing the major DP growth areas, physical IO transfer sizes will likely remain small and therefore realize minimal IO performance improvements with faster channels.

f) Traditionally DASD performance analysts look to reducing start IO queing, reducing arm seek motion delays, or reducing data path contention and rotational position sense (RPS) reconnect times. The 6 and 10 MB/s channels result in modest IO throughput improvements, more so with the 2X 10 GB configurations.

Dramatic throughput improvements are realized when data transfer sizes are 47 KB. The 1X configurations continue to yield more data volume than their 2X counterparts, but the difference is trimmed to about 5%. Channel busy percentiles also rise with the 47 KB transfer sizes.

Sustained throughput increases with the faster device transfer speeds. Unlike the 4 KB scenarios, 47 KB transfer times constitute a larger proportion of total IO service time and stand to gain significant time reductions with 4.5, 6 or 10 MB/s transmission speeds. If the 1X and 2X configurations run with 10 MB/s channels, sustained throughput more than doubles when compared with conventional 3 MB/s channels. Figure 2 summarizes the maximum through-puts discussed above.

Impressive as the large transfer size throughputs are, the impact on overall system improvement, as related to faster channels of the future, is surprisingly limited. The storage application growth for commercial data processing is precisely where the performance gain of faster channels is at its worst, namely the online database and interactive environments.

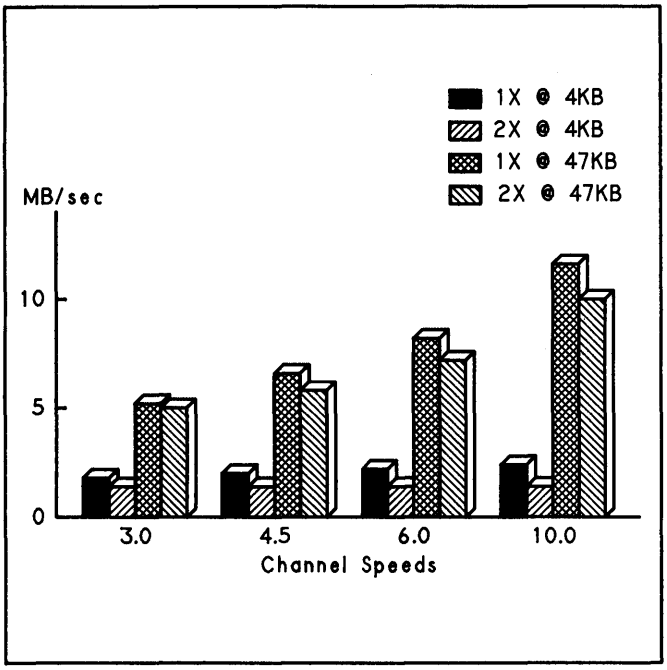

Figure 2. Maximum Throughputs
4 KB vs. 47 KB Transfer Sizes

Figure 3 depicts past and future storage requirements for batch, database, and system data [3]. Based on GUIDE customer surveys, databases account for 42% of disk volume usage in 1978, 55% in 1984, and 68% by 1990. Conversely, batch applications shrink from 40% in 1978, to 24% in 1984 and down to 8% by 1990. For the same time periods, total gigabytes of DASD for large installations increase from 9 GB, to 102 GB, and a sizable projected value of 1157 GB by 1990. The reality is that database

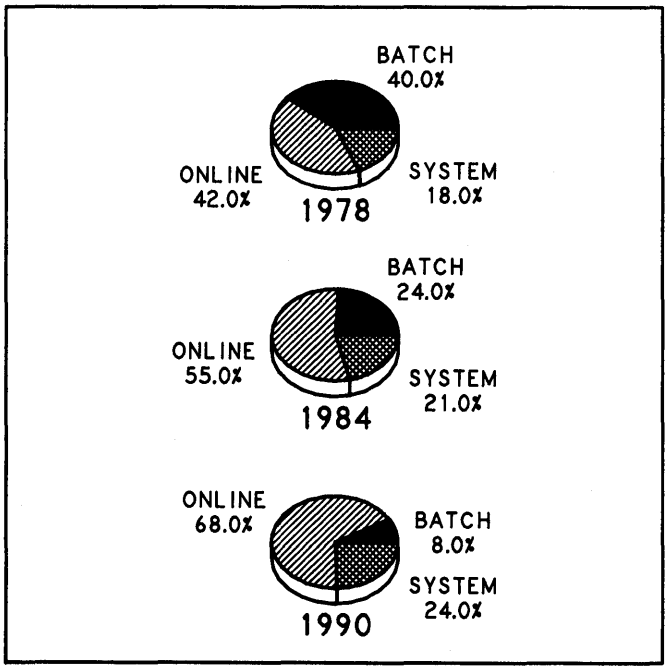

Figure 3. DASD Storage Growth
GUIDE Survey Data

and interactive users simply do not require more than 2 KB or 4 KB of data at a time. This is especially true when the data has a random pattern coupled with a low locality of reference profile. Relational databases, for example, use small IO data transfer sizes.

Throughout this analysis the IO workloads were stochastically balanced across all available volumes. Skewed IO workloads have a significant impact on throughput and response times, the details of which have been presented in a previous paper [1].

We conclude that faster data transmitting devices are well suited for large IO blocksize applications, typically being batch in nature or non-productive utility activity such as copying data from disk to tape or another disk. We further conclude that an increase in the number of channels supported will accommodate the need for more parallelism in the commercial application mainframe arena. Singh, King, and Anderson discuss the increasing importance of overlapping functions and maintaining a balance between processors and storage subsystems [4].

QUAD PORT ANALYSIS

We consider 10 GB disk configurations with 1X and 2X devices, using a total of four channels, four directors and four heads of string. The base cases represent a pair of dual ported configurations and are contrasted to quad port subsystems which allow any of the four data paths to access any disk device address.

The open loop model uses a driver generating an aggregate average of 150 SIO/sec. Response time results appear in Table 2 and Figure 4. We vary channel speeds and data transfer sizes. Stochastically random seek arm motion occurs 50% of the time, with zero seek times for the remaining 50%.

Qd = Quad Port

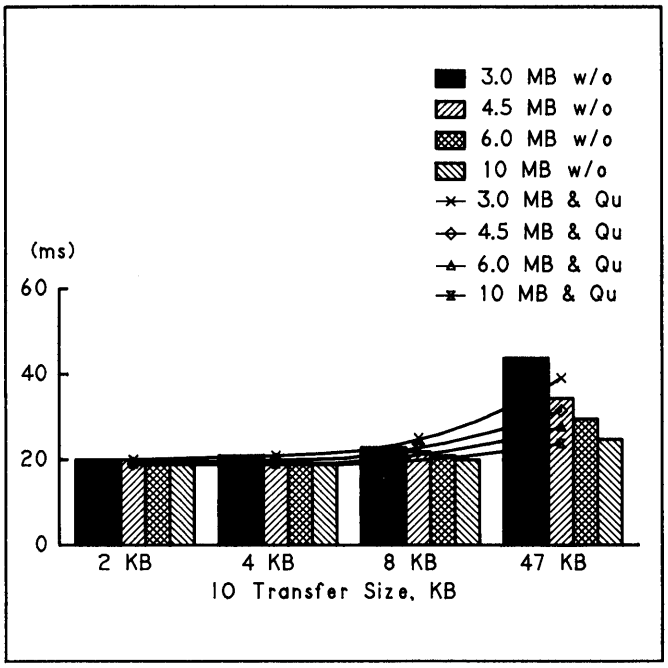

Figure 4. Quad Port Impact on Response Time
1X, 4X16, 150 SIO/sec

A number of interesting observations are made:

a) Quad port is more effective with 3 MB/s channels than with the faster channels. The faster channels, by definition, will have lower utilization, and therefore less probability of being unavailable. This suggests alternate data paths may not be used as frequently with the 4.5, 6, and 10 MB/s channels as they are for conventional 3 MB/s datastreaming channels.

b) The 2KB data transfer size IO response times realize no performance improvement with quad ports. Small physical block transfer sizes tend to make the disk drives the bottlenecks, not the channel and director data paths. In the 4KB cases, as well, hardly any improvement in response time occurs. Only in the 47 KB cases are there significant response time improvements.

c) The 47 KB blocksizes represent a full track of today's 1X or 2X devices. At 3 MB/s channel speeds, response time improves by 12.5% for the 1X configuration. With 10 MB/s channels, the quad port improvement reduces to about 3%.

d) We conclude that quad ports offer little performance improvement for blocksizes of 8 KB or smaller, and that faster future channels gain very little from quad ports.

While the performance associated with quad ports may not be dramatic on rotating disks, solid state disk subsystems stand to gain considerably, especially when channel utilizations are consistently high (in the 60% to 80% range). With the exception of nominal channel interface protocol and search overhead time, literally all solid state disk device service time is connected data transfer time. Faster channels will have significant improvements for paging and non-paging data sets residing on solid state IO devices. Figure 5 depicts the impact of faster channels on IO response times for a 1X cached subsystem of rotating disks versus an identical workload on a solid state disk subsystem. The cached configuration and workload characteristics are described in detail under the 'Cached Controller and Faster Channels' section of this paper. Note the significant percentage of improvement in IO response time as channel data transfer speed increases. Conversely the rotating disks with faster cache controller transfer speeds realize marginal response time improvements.

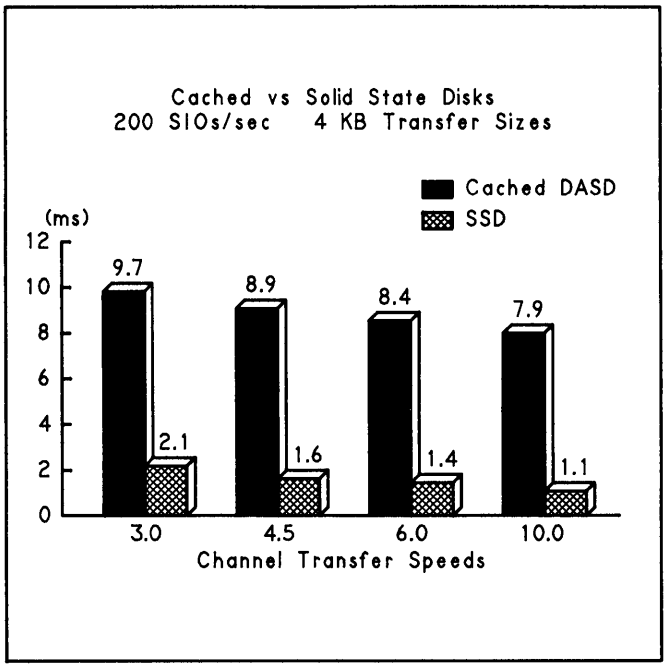

Figure 5. Faster Channels & I/O Response

Performance for rotating disks will not be the main attraction with quad porting; data connectivity will likely be the greatest advantage of quad ports. Instead of supporting one alternate data path to a given disk volume, future versions of operating systems will enjoy three alternate paths.

ONLINE AND BATCH IO RESPONSE TIMES

Table 3 summarizes average IO response times for two-director subsystems while varying data transfer speeds. IO workload rate is held constant at 150 SIO/sec with a Poisson distribution modified arrival rate. The 2 KB and 4 KB physical IO transfer sizes represent nominal blocksizes for online and interactive data access environments, while the 8 KB transfer sizes represent batch IO requests.

Small online data transfer sizes result in minimum improvements in response times, for reasons discussed previously. Channel utilizations show more significant improvements as the same IO workload is run on progressively faster channels and devices. The 1X configurations continue to outperform their 2X counterparts because sixteen actuators continue to be better than eight when the drives are the subsystem bottlenecks.

With 8 KB transfers, the faster transfer speeds show more improvement in IO response times. Larger blocksizes suggest that the data transfer ('connect time' in RMF terminology) component accounts for a significant portion of total IO service time. Faster channels and transfer speeds account for a drop in response time from 27.2 ms with 3 MB/s to 21.5 ms with 10 MB/s -- a 21% improvement. The equivalent 2X 10 Gigabyte configurations have worse response times but show comparable percentage gains with faster data paths.

Table 3. 150 SSCH/sec / 2K 4K 8K / 3, 4.5, 6, 10 MB/sec
Average Response Times

1X 2 x 16 Configuration

DATA TRANSFER SPEED	2 KB		4 KB		8 KB	
	TR ms	CHANS	TR ms	CHANS	TR ms	CHANS
3 MB/s	21.7	15.2%	22.9	20.3%	27.2	30.6%
4.5	20.7	13.5	21.7	17.0	40.2	23.8
6	20.5	12.7	21.2	15.2	22.9	20.3
10	20.1	11.6	20.6	13.1	21.5	16.2

2X 2 x 8 Configuration

DATA TRANSFER SPEED	2 KB		4 KB		8 KB	
	TR ms	CHANS	TR ms	CHANS	TR ms	CHANS
3 MB/s	26.7	15.2%	28.9	20.3%	35.3	30.6%
4.5	26.0	13.5	27.5	17.0	30.6	23.8
6	25.8	12.7	26.7	15.2	28.9	20.3
10	25.4	11.6	26.1	13.1	27.2	16.2

TR = average response times
50% Zero Seeks

We conclude that batch applications with larger transfer sizes will see moderate response time gains with faster channels; batch IO workloads will likely experience more improvement than online or interactive applications. The biggest gain occurs where it is less needed, in terms of storage growth directions.

MORE VS FASTER CHANNELS

We compare IO response times at 150 SIO/sec for four channel subsystem configurations in Table 2 to response times for two channel configurations in Table 3. Looking at 8 KB transfers, the 1X configuration in Table 2 shows average response time of 23.4 ms with four conventional 3 MB/s channels. Table 3 shows 22.9 ms for two 6 MB/s channels, an insignificant difference of 0.5 ms. Note that in each configuration total channel bandwidth is constant at 12 MB/s. Similarly the 2 KB scenarios show even less response time improvement with 6 MB/s channels.

Aggregate IO subsystem performance is just as easily accomplished with increasing the number of conventional datastreaming channels as opposed to increasing device and data path transmission speeds.

CACHED CONTROLLERS AND FASTER CHANNELS

An architectural alternative is to support faster channel transfer rates only for cache hit data, and not for data read or written directly to rotating disk devices. In this analysis we consider four cache controller workload profiles:

1) IOs with a 9:1 ratio of reads to writes, and 90% read hit probability. This is designated as a "90/90" column header in Table 4.
2) IOs with a 9:1 read to write ratio and a 75% read hit probability, or "90/75" in Table 4.
3) IOs with a 4:1 read to write ratio and a 75% read hit rate, or "80/75".
4) A marginal cache controller potential with an IO pattern of roughly 2:1 reads to writes and 75% read hit rate, or "70/75".

All direct or native IO to the 1X and 2X disk configurations use the conventional 3 MB/s data transfer rate. 50% of all seeks are random with the remaining seek times being zero. Workload arrival rates to the subsystems vary from a light load of 50 SIOs per second, and increase in increments of 50, up to a maximum of 200 per second. Tables 4 and 5 summarize response times for 4 KB data transfer sizes, for 1X and 2X devices, respectively. Tables 6 and 7 summarize analagous response times for 2 KB transfer sizes.

Table 4. 4 KB: Average Response Time, Cached Controllers

1X 2 x 16 Configuration

TRANSFER SPEED	SSCH/sec	90/90	90/75	80/75	70/75
3 MB/s	50	6.0 ms	9.1 ms	10.2 ms	11.4 ms
3	100	6.9	11.2	12.5	13.4
3	150	7.8	16.5	16.9	18.2
3	200	9.7	30.5	29.3	28.4
4.5	50	5.6	8.7	9.9	11.2
4.5	100	6.4	10.8	12.0	13.3
4.5	150	7.2	15.3	16.1	17.2
4.5	200	8.9	26.9	25.4	26.9
6	50	5.4	8.5	9.7	11.0
6	100	6.2	10.6	11.8	12.9
6	150	7.0	15.1	16.1	17.0
6	200	8.4	26.0	24.4	25.9
10	50	5.2	8.3	9.6	10.8
10	100	5.9	10.3	11.5	12.6
10	150	6.6	14.1	15.5	16.4
10	200	7.9	22.6	23.4	25.2

Table 5. 4 KB: Average Response Time, Cached Controllers

2X 2 x 8 Configuration

TRANSFER SPEED	SSCH/sec	90/90	90/75	80/75	70/75
3 MB/s	50	6.5 ms	10.2 ms	11.3 ms	12.6 ms
3	100	7.8	13.2	14.8	16.1
3	150	9.3	20.7	22.3	23.3
3	200	12.3	42.9	40.8	44.7
4.5	50	6.1	9.7	11.0	12.3
4.5	100	7.5	12.6	14.3	15.6
4.5	150	8.8	19.6	20.9	22.2
4.5	200	11.0	38.7	38.8	39.9
6	50	5.9	9.7	10.8	12.2
6	100	7.1	12.5	14.1	15.5
6	150	8.4	18.6	20.4	22.2
6	200	10.6	36.6	27.5	38.3
10	50	5.7	9.5	10.6	12.0
10	100	6.8	12.1	13.9	15.4
10	150	8.1	17.8	19.7	21.1
10	200	10.3	32.1	35.2	35.1

We notice the longest average response times occur when the cache profiles are poorest -- the 70/75 scenarios described above. For example, in Table 4 for 3 MB/s transfer speeds response time at 200 SIO/sec is 9.7 ms averaged for all IOs with the 90/90 cache profile, compared to 28.4 ms with the 70/75 profile.

Table 6. 2 KB: Average Response Time, Cached Controllers

1X 2 x 16 Configuration

TRANSFER SPEED	SSCH/sec	90/90	90/75	80/75	70/75
3 MB/s	50	5.3 ms	8.3 ms	9.4 ms	10.6 ms
3	100	6.0	10.2	11.3	12.4

6	50	5.0	8.1	9.2	10.4
6	100	5.7	9.9	10.9	12.1
6	150	6.4	13.1	14.2	15.3
6	200	7.6	20.3	21.1	21.2
10	50	4.9	8.0	9.1	10.3
10	100	5.5	9.8	10.8	11.9
10	150	6.2	12.9	13.9	15.5
10	200	7.4	20.3	20.1	21.2

Table 7. 2 KB: Average Response Time, Cached Controllers

2X 2 x 8 Configuration

TRANSFER SPEED	SSCH/sec	90/90	90/75	80/75	70/75
3 MB/s	50	5.8 ms	9.4 ms	10.4 ms	11.7 ms
3	100	6.9	12.4	13.5	14.8
3	150	8.1	18.2	19.0	20.5
3	200	10.2	32.1	31.3	32.8
4.5	50	5.6	9.2	10.3	11.6
4.5	100	6.7	11.6	13.3	14.7
4.5	150	7.9	17.0	18.1	20.2
4.5	200	9.7	29.4	29.7	31.7
6	50	5.5	9.2	10.2	11.5
6	100	6.5	11.4	13.0	14.5
6	150	7.7	17.2	18.2	19.6
6	200	9.5	29.2	28.8	31.1
10	50	5.4	9.1	10.1	11.4
10	100	6.4	11.5	12.8	14.1
10	150	7.5	16.4	18.3	19.2
10	200	9.3	27.6	29.1	30.1

Of more interest is the overall small improvement with faster channels. For the same workload at 200 IOs per second, and our best cache case of 90/90, response time improved from 9.7 ms to 8.9 ms with 4.5 MB/s channel speed. 6 MB/s channels reduced response time an extra 0.5 ms to 8.4 ms, and 10 MB/s channels down to 7.9 ms.

As the cache profiles degrade, the performance impact of faster channels is further diminished with cache controller subsystems (Figure 6). In the marginal 70/75 cache scenarios, response time improvement at 200 IOs per second arrival workload is 11%, at best, and this is with 10 MB/s vs 3 MB/s channels. Channel interface protocol overhead remains constant at 1.4 ms, thus continuing to diminish improvements intuitively expected with faster channels.

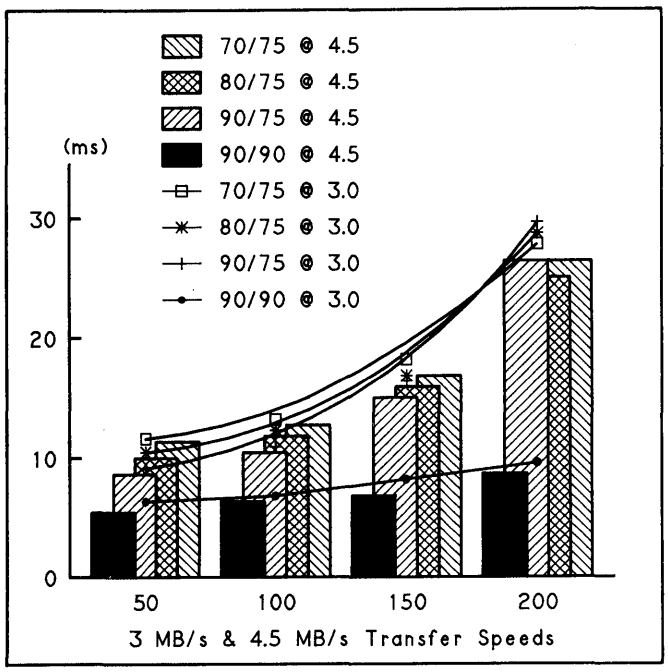

Figure 6. 1X DASD Response Times
4 KB, Cached, 2X16, 50% Zero Seeks

Table 5 summarizes average response times for the 2X 10 GB configurations. The double capacity devices consistently show longer response times for identical workloads and cache profiles, as compared to the 1X configurations of Table 4. Note how much more rapidly the decay in average IO response times occurs as the cache profile deteriorates from 90/90 to 90/75 and beyond. Reducing the number of servers by half with 2X disk devices, and incurring peaks of 200 IOs per second can have a debilitating affect on cached subsystem response time. Faster channels do not address the bottleneck, and the bottleneck is the device itself when data transfer size is 4 KB or smaller.

Using 2 KB data transfer sizes is of interest with cached IO subsystems. The notion of achieving more read hits per staged track with small physical blocksizes is appealing in a cached IO environment. For instance, in Table 6 the 200 SIO per second workload at 3 MB/sec results in an average response time of 8.1 ms. Compared to the same scenario in Table 4 with 4 KB blocksizes, response time improves by more than 16%.

Most of this improvement is attributable to the cache controller and the 90/90 IO workload profile. Increasing channel speeds with 2 KB transfer sizes results in marginal response time improvements, for reasons discussed previously. The 90/90 profiles can be attained by carefully selecting the right files for cached subsystems. Best file candidates are [3]:

* TSO: Libraries, ISPF, catalogs, user data
* IMS: ACB, PSB, MFS, ADF work data base, program libraries
* CICS: Program libraries
* General System: Partitioned data sets, PROCLIB, master and user catalogs, control data sets (RACF, DFHSM).

A point of interest on the cached subsystem response times. On Table 5, for example, note that response time for the 3 MB/s channel speeds and 200 IOs per second workload were actually better for the 80/75 cache profile than for the 90/75 cache profile. At first, we might

expect the profile with the better read to write ratio of IOs to have better response times, the opposite of what occurred. The 90/75 profile has a response time of 42.9 ms, as opposed to the 40.8 ms of the 80/75 profile.

This phenomenon is explainable when we consider the expected number of disk to cache track stages. Multiplying 200 SIOs per second by .9 we determine the number of read IOs to be 180; similarly the 80/75 profile results in only 160 read IOs. Since we have cache hit rates of 75% in each case, we can expect to incur misses the remaining 25% of the time. Misses, by design, result in cache track stages; there will actually be more cache track staging in the 90/75 case than in the 80/75 case: 45 stages vs 40 stages, respectively (Table 8). In heavily loaded subsystems, the effect on overall performance can indeed be worse with 'better' cache workload profiles. The weakness of cache controllers is the increased device to cache director utilizations. The impact of a cached subsystem with insufficient megabytes of memory is more important at times than the ratio of reads to writes.

Table 8. Cache Controller Results, Tables and Graphs

Symbol	Definitions
	90/90 9% Reads, 10% Writes, and 90% probability of cache read hits
90/75	90% Reads, 10% Writes, and 75% probability of cache read hits
80/75	80% Reads, 20% Writes, and 75% probability of cache read hits
70/75	70% Reads, 30% Writes, and 75% probability of cache read hits

Example

Case A: At 20 SSCH/sec, and 80/75 profile:
Estimated # Reads = 200 x (.8) = 160 reads/sec
Estimated # Writes = 200 x (.2) = 40 writes/sec
Estimated # Read Stages = 160 (1.0 - .75) = 40 Cache States/sec

Case B: At 200 SSCH/sec, and 70/75 profile:
Estimated # Reads = 200 x (.7) = 140 reads/sec
Estimated # Writes = 200 x (.3) = 60 writes/sec
Estimated # Read Stages = 140 (1.0 - .75) = 35 Cache States/sec

Observation: Case A, with a better read to write ratio than Case B, will experience more data path contention than Case B.

OTHER MODEL ASSUMPTIONS

- 50% zero seek arm movements
- Poisson arrival rate distributions
- GPSS V Monte Carlo Discrete Event Simulation
- Data transfer sizes held constant within a simulation run

We can state that traditional cache workload characteristics influence subsystem performance considerably more than faster channels will. Choosing the best file candidates for cached devices continues to be a key factor in improving performance.

CONCLUSION

Faster data transfer times on rotating disk subsystems will probably have maximum benefit in the slowest growing portion of the data storage environment -- batch applications with large or chained IO blocks. To achieve significant throughput and response time improvement, large data transfer sizes must be exploited.

Solid state IO subsystems stand to gain more from faster channels, even with small data transfer sizes, since the bulk of their total IO service time is electronic data transfer, without any mechanical and disconnected overhead times. Quad porting has maximum performance gain with solid state systems, but the dominant feature with quad porting is connectivity.

Single and double capacity disk devices perform well, however there are performance differences when IO workload intensity and data transfer sizes are varied. A mix of both device types with and without cache controllers is desirable, allowing an informal and transparent hierarchy of isolated disk pools to accommodate the needs of batch, interactive, and online file applications.

The adventure of improving IO performance is far from over! Configuration tuning via hardware selection and file placement continues to offer plenty of opportunity in providing better IO service times as newer and faster processors are introduced.

An Intuitive Approach to Performance Prediction with Application to Workload Management in VM SP/HPO

Joseph Hellerstein

IBM Thomas J. Watson Research Center

ABSTRACT

Workload management can be greatly facilitated by using predictive models to anticipate the impact on system resources when workloads are assigned to computer systems. In the IBM operating system VM SP/HPO (Virtual Machine System Product with High Performance Option), contention for the first 16 megabytes of storage is often a major performance problem, and its resolution often requires workload management. Such storage contention is indicated by three variables: page steals from the low demand paging area, (LOSTEALRAT), free storage extends (FREXTND), and prime free utilization (PRIMEUTL). We know of no existing predictive model for these variables. Herein, we outline our efforts to use a statistical approach to construct such a model, and we present an apparently new technique which has been developed in the process - **non-parametric interpolative-forecasting for monotone functions (NIMF)**. Although NIMF is discussed in the context of VM SP/HPO performance analysis, it is a generally applicable statistical technique. Indeed, we have used NIMF to analyze data from MVS/XA systems.

Our attempts to use least squares regression to predict LOSTEALRAT have met with little success, primarily because of an inability to find an algebraic expression relating LOSTEALRAT to the workload variables (number of logged-on users and total virtual machine IO rate). However, the regression studies do indicate that LOSTEALRAT is monotonically increasing in the workload variables. When such a monotone relationship exists, an intuitive approach often used by performance analysts is to bound a predicted value by using the monotone relationship to select a lower and upper bound from the measurement data. This idea motivated the development of NIMF. A NIMF model only requires specifying a monotone relationship between the independent and dependent variables. Using data from several VM SP/HPO 4.2 systems, NIMF and regression are compared as to their accuracy of predicting contention for the first 16 megabytes of storage. These studies indicate that NIMF can be as accurate as a good regression model. However, formulating NIMF models is much easier than formulating regression models since NIMF only requires specifying a monotone relationship between independent and dependent variables while regression requires an algebraic relationship. We conclude by using NIMF to determine how workload can be managed to control LOSTEALRAT in a large VM SP/HPO system.

1. Introduction

An important aspect of managing a computer installation is workload management which involves assigning workloads (e.g., interactive users) to computer systems so that system resources (e.g., CPU, IO devices, storage) are not over-utilized. Since moving workloads is time consuming and disruptive, it is desirable to have tools which can predict the resource impact of increasing or decreasing workload. Numerous pre-packaged models exist for predicting the utilizations of CPUs, channels, control units, and devices (e.g., BEST/1 [BGS 84], VM Performance Planning Facility [IBM 84]). VM SP/HPO (Virtual Machine System Product with High Performance Option) is an IBM operating system which is widely used for interactive computing. Large VM SP/HPO systems are often constrained by contention for the first 16 megabytes of storage. Unfortunately, existing computer-performance prediction models are not adept at predicting storage contention. Indeed, we know of no existing model which predicts the effects of contention for the first 16 megabytes of storage in VM SP/HPO. Herein, we describe a statistical approach to predicting such storage contention. This approach is based on an apparently new technique, **non-parametric interpolative-forecasting for monotone functions (NIMF)**, which is described in this paper. Although NIMF is presented in the context of analyzing VM SP/HPO performance, NIMF is a generally applicable statistical technique. Indeed, we have used it to analyze data from MVS/XA systems.

A major reason for the absence of an existing model for contention for the first 16 megabytes of storage is that the commonly used techniques for constructing predictive models (e.g., queueing theory [Kleinrock 75], operational analysis [Denning and Buzen 78], and regression [Draper and Smith 68]) require formulating an algebraic relationship between the dependent variables (e.g., contention for the first 16 megabytes of storage) and the independent variables (e.g., workload). Unfortunately, contention for the first 16 megabytes of storage has a complex relationship to workload, and this is difficult to formulate as an algebraic expression. However, we do expect storage contention to increase with workload. This observation has motivated the development of NIMF. A NIMF model only requires specifying a **monotone relationship** which indicates the directional effect on the independent variable (i.e., increases or decreases) when a dependent variable increases. NIMF models are easy to formulate, and our experience suggests that their accuracy is comparable to that of a good regression model.

The remainder of this paper is organized as follows. Section 2 discusses contention for the first 16 megabytes of storage in HPO 4.2. Section 3 outlines our attempts to construct regression models for one aspect of contention for the first 16 megabytes of storage (low-DPA page steal rates). These attempts were not successful primarily because we could not find a good algebraic expression relating low-DPA page steal rates to the workload variables. NIMF is described in section 4. Section 5 presents several case studies in which the accuracy of NIMF is compared to that of regression for predicting contention for the first 16 megabytes of storage. Section 6 gives an overall assessment of NIMF. Section 7 applies NIMF to managing workload in a large VM SP/HPO system so as to control low-DPA page steal rates. Our conclusions are contained in section 8. Appendix A summarizes the symbols used in this paper.

This paper is targeted for two audiences - computer performance practitioners and data analysis experts. As such, sections are written at different levels of detail. Specifically, computer performance practitioners may prefer skipping the mathematical details in the latter part of section 4.1; the examples provided in 4.1 should be sufficient to illustrate the NIMF technique. On the other hand, data analysis experts may be particularly interested in the detailed discussion contained in section 4.1.

2. Low-Memory Storage Contention in VM SP/HPO 4.2

High-end mainframes have large amounts of main memory (e.g., 64 megabytes), and there may be expanded storage as well (see Fig. 1). However in VM SP/HPO, the operating system (CP) uses 24 bit addressing and so can directly address only the first 16 megabytes of main memory. Thus, CP control structures must have addresses less than 16 megabytes regardless of the size of main memory. In high-end systems, this restriction can create contention for the first 16 megabytes of storage. Three key components of this storage in VM SP/HPO 4.2 are:

- Low Demand Paging Area (DPA) - used by a variety of system services (e.g., Inter-User Communications Vehicle)
- Free Storage Area - used by CP for control structures such as swap tables, virtual device tables, and pointers to spool files
- Prime Free Storage - a sub-area of free storage which is used by CP as a fast-path through the free-storage buffer manager

Low DPA, free storage, and prime free storage have dynamic demands placed on them; so from time to time their configured sizes are insufficient to satisfy these demands. An indication that low DPA is too small is when a page request must be satisfied by stealing a page from a user in the multi-programming set (referred to as an in-queue user); the rate at which this occurs is the **low-DPA page steal rate**. When free storage is too small, a page is allocated from low DPA. This is called a free storage extend, and the rate at which this occurs is the **free storage extend rate**. Extends are undesirable because they: (a) cause additional CP overhead and (b) increase spin-lock waits in multi-processor systems. When prime free storage is too small, a prime miss occurs and the buffer request must be satisfied by non-prime free storage. Doing so increases CP overhead. We assess contention for prime free storage by **prime free utilization** which is the fraction of prime free storage which is allocated. Thus, contention for the first 16 megabytes of storage can be gauged by looking at the low-DPA page steal rate (denoted by the variable **LOSTEALRAT**), free storage extend rate (denoted by the variable

Fig. 1: Overview of VM/HPO 4.2 Systems Studied

Characteristic	VMSYS1	VMSYS2	VMSYS3
CPU	3090-200	3081K	3081K
Main Memory	64 Meg.	64 Meg.	64 Meg.
Expanded Store	128 Meg.		
Workload	CMS	CMS	PROFS

CMS = Conversational Monitor System
PROFS = Professional Office System

FREXTND), and prime free utilization (denoted by the variable **PRIMEUTIL**).

Sometimes contention for the first 16 megabytes of storage can be significantly reduced by tuning. For example, if the low-DPA page steal rate is large (e.g., > 5/second), and there are no extends or prime free misses, then the free storage area can be reduced [Hoag 86]. However, when there are low-DPA page steals, extends, and prime misses, tuning becomes much more problematic and workload management should be considered.

But how much must the workload be reduced to achieve a specified level of contention? Since moving workloads is time consuming and disruptive, there is benefit in predicting what the level of contention for the first 16 megabytes of storage would be after reducing workload by a specified amount. Constructing such a predictive model requires first characterizing the workload. Here we use the following high-level characterization:

1. Fixed demands imposed by virtual machines (e.g., swap tables and virtual devices).
2. Variable demands due to the activity level of the virtual machines (e.g., CP service requests and CCW translation).

Our measure of fixed demands is the number of logged-on virtual machines[1] (**LOGGED**), and our measure of variable demands is the total VIO rate of all virtual machines (**VIO**). The Virtual Machine Monitor Analysis Program (VMMAP) reports FREXTND, PRIMEUTIL[2], LOGGED, and VIO [IBM 85]. LOSTEALRAT is computed from two variables reported by VMMAP:

$$\text{LOSTEALRAT} = \text{STEALRATE} - \text{HISTEALRAT} \quad (1)$$

Where:
STEALRATE = Total page steal rate (above and below 16 megabytes)
HISTEALRAT = Page steal rate for pages above 16 megabytes

Fig. 1 characterizes three VM systems from which data were collected. For each system, data were collected on several days with variable values averaged over fifteen minute intervals. We use these data to evaluate models for predicting the dependent variables LOSTEALRAT, FREXTND, and PRIMEUTIL from the independent variables LOGGED and VIO.

3. Attempts to Find a Regression Model for Low-DPA Page Steal Rate

Least squares regression (hereafter, just regression) is a commonly used statistical technique in which an algebraic expression is fit to a set of measurement data. We represent measurement instances as ordered pairs of the form $(y_1, X_1), \ldots, (y_I, X_I)$ where y_i is the i-th instance of the **dependent variable** to predict (e.g., LOSTEALRAT_i) and $X_i = (x_{i1}, \ldots, x_{iJ})$ is a vector of **independent variables** or predicting variables (e.g., $(\text{LOGGED}_i, \text{VIO}_i)$). Regression requires that the dependent variable be related to the independent variables by an algebraic expression. The general form is

$$y_i = f(X_i) + \varepsilon_i \quad (2)$$

Where:
f = function with a known form
$\varepsilon_1, \ldots, \varepsilon_I$ = error terms which are independent random variables from the same normal distribution with mean 0

For example, if LOSTEALRAT is hypothesized to be a linear function of LOGGED and VIO, the regression equation is:

$$\text{LOSTEALRAT}_i = b_0 + b_1\text{LOGGED}_i + b_2\text{VIO}_i + \varepsilon_i$$

[1] Of course the number of logged-on users does not account for all fixed demands (e.g., spool files) nor does it account for effects due to virtual machine size (e.g., swap tables). However, our experience is that it is a good approximation.

[2] VMMAP does not assign a variable name to prime free utilization. PRIMEUTIL is a name is of our own creation.

Fitting a least squares regression model to a set of measurement data involves choosing the b_j so as to minimize (in a least squared sense) the deviation of y_i from its estimated value. When a regression model is fit to a set of measurement data, the quality of the fit can be assessed by R^2 which is the fraction of the variability in the data which is accounted for by the regression model. We want R^2 to be as close as possible to 1; a reasonable model should have R^2 much larger than .5.

Using regression to do predictions involves: (1) having a set of **base measurement data** from which each b_j is estimated and (2) computing an estimate for an unknown y^* by substituting the values for its associated X^* into the fitted regression equation. In addition, we want a range of y values that contains y^* with a specified level of confidence. This is referred to as a **prediction interval** and is specified by a lower bound, y_L, and an upper bound, y_H. The probability of y^* being within the prediction interval is the **confidence level** of the prediction interval. We write the confidence level as $1-\alpha$ (e.g., for a 75% confidence level, $\alpha = .25$). Thus, $Pr[y_L \le y^* \le y_H] \ge 1-\alpha$. We obtain prediction intervals for regression by constructing confidence intervals for the expected value of y^*. (See [Draper and Smith 68] for a discussion of regression confidence intervals.) To summarize:

Obtaining Prediction Intervals Using Regression

Given

$y_1, \ldots, y_I$ = dependent variables with $y_I = f(X_I) + \varepsilon_I$
$X_1, \ldots, X_I$ = vectors of independent variables with $X_I = (x_{I1}, \ldots, x_{IJ})$
f = function with a known form
$\varepsilon_1, \ldots, \varepsilon_I$ = error terms which are independent random variables from the same normal distribution with mean 0
$1-\alpha$ = confidence level
X^* = values of independent variables for an unknown y^*

Find

y_L and y_H such that $Pr[y_L \le y^* \le y_H] \ge 1-\alpha$.

Building a regression model for LOSTEALRAT begins with attempting to formulate an algebraic expression relating LOGGED and VIO to LOSTEALRAT. Unfortunately, we have little intuition about the form of such an algebraic expression. Fig. 2 shows LOSTEALRAT plotted separately against LOGGED and VIO. We see no obvious algebraic form for the relationship, although it does appear that LOSTEALRAT is increasing in both LOGGED and VIO.

Lacking intuition on a specific algebraic expression, we use a very general approach - approximating an unknown function by a polynomial [de Boor 78]. Our strategy is to consider polynomials of increasingly higher degree until there is little increase in R^2. We consider the following models:

R1: $y = b_0 + b_1L + b_2V + \varepsilon$
R2: $y = b_0 + b_1L + b_2V + b_3L^2 + b_4LV + b_5V^2 + \varepsilon$
R3: $y = b_0 + b_1L + b_2V + b_3L^2 + b_4LV + b_5V^2 + b_6L^3 + b_7L^2V + b_8LV^2 + b_9V^3 + \varepsilon$

Where:
y = dependent variable (LOSTEALRAT in this case)
L = LOGGED
V = VIO

Fig. 3 summarizes the results of evaluating R1, R2, and R3 for the VMSYS1 base measurement data using GRAFSTAT [Schatzoff and Lane 86]. After exploring a variety of data transformations as recommended in [Daniel and Wood 80] (e.g., taking logarithms, excluding outliers), the highest R^2 is still fairly small[3]-only 37%. Also, while there is a big increase in R^2 from R1 to R2 (25% to 35%), the increase from R2 to R3 is quite small (35% to 37%); this gives us little confidence of improving the model by using polynomials of higher degree. Furthermore, it is hard to interpret these models. For example in R3, why is V^2 significant while V is not, and why is LOSTEALRAT decreasing in $I.V^2$?

If there exists a good algebraic expression relating LOSTEALRAT to LOGGED and VIO, R^2 could be increased. Possibly if sufficient effort were expended such an algebraic expression could be formulated. However, Fig. 4 suggests that knowing this would not help with discovering an algebraic relationship be-

[3] Actually, some transformations do increase R^2 (e.g. $\sqrt{y}$), but the ones that we investigated also increase the width of the prediction intervals.

V = VIO (total virtual machine VIO rate)
bold = significant at .1 level

tween FREXTND and LOGGED, VIO or an algebraic relationship between PRIMEUTIL and LOGGED, VIO. Thus, still more effort would be necessary to construct these models. Even more discouraging is the concern that the specific algebraic relationship may change with the software release and patches applied to the system. These observations make us very pessimistic about finding an acceptable regression model for predicting contention for the first 16 megabytes of storage based on LOGGED and VIO.

4. Non-parametric Interpolative-forecasting for Monotone Functions (NIMF)

Our difficulties with regression stem from its requiring us to provide something that we do not know - an algebraic expression relating LOSTEALRAT to LOGGED and VIO. However, we do believe that LOSTEALRAT (as well as the other measures of contention for the first 16 megabytes of storage) increases with LOGGED and VIO.

Ideally, we want a technique which produces prediction intervals but which only requires specifying directional effects (e.g., LOSTEALRAT increases with LOGGED and VIO). Informally, a **monotone relationship** specifies the direction in which the independent variables must change in order to increase the dependent variable. For example,

MR1: LOSTEALRAT increases when at least one of LOGGED and VIO increase and neither decreases

We say that y is a **monotone function** of X if there is a monotone relationship between y and X. More formally, a function f is monotone if for all j the derivative of f with respect to x_j, $\frac{\partial f}{\partial x_j}$, never changes sign.

Our central observation is that **monotone relationships can be used to bound a predicted value based on measurement data.** This is best illustrated by example.

Example 1: Obtaining Prediction Intervals using Monotone Relationships

We can bound an unknown value of LOSTEALRAT (denoted by LOSTEALRAT*) when LOGGED$^* = 500$ and VIO$^* = 500$ based on MR1 and the following data:

Entry #	LOGGED	VIO	LOSTEALRAT
1	482	486	.3
2	510	611	1.5

Specifically, if we assume that MR1 always holds, then a lower bound for LOSTEALRAT* is LOSTEALRAT$_1$ (= .3) since:

1. LOSTEALRAT is increasing in LOGGED and VIO (MR1)
2. LOGGED$_1$ = 482 < 500 = LOGGED* and VIO$_1$ = 486 < 500 = VIO*.

Similarly, LOSTEALRAT$_2$ (= 1.5) provides an upper bound since LOGGED$_2$ = 510 > 500 = LOGGED* and VIO$_2$ = 611 > 500 = VIO*.

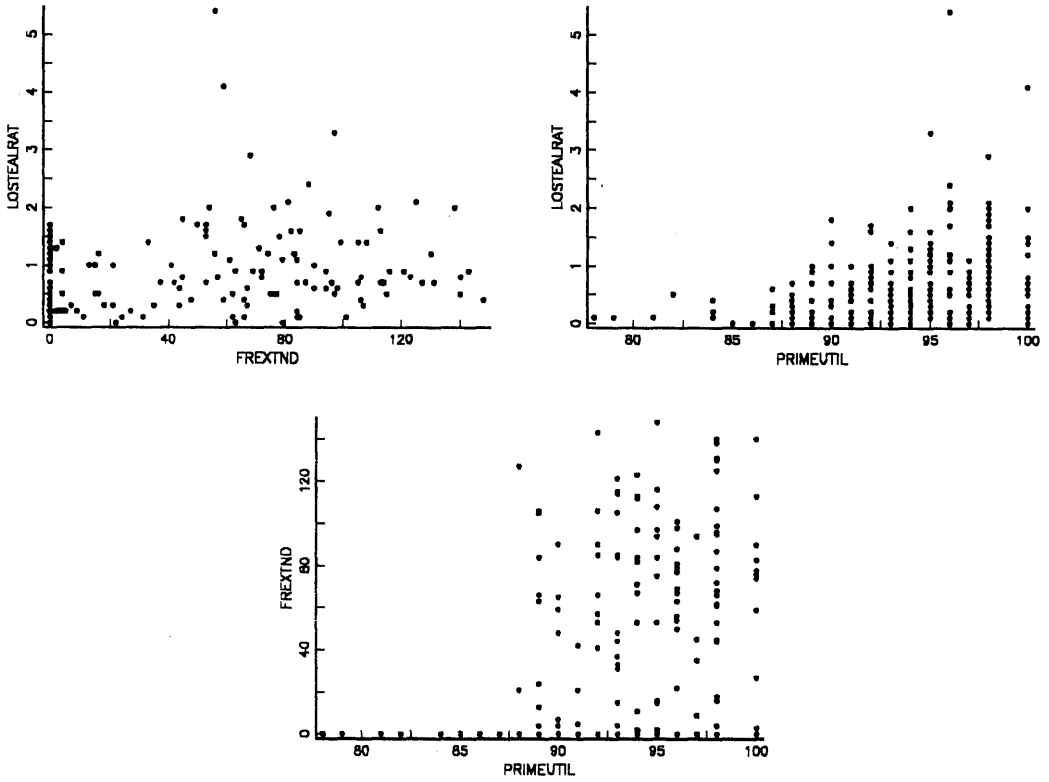
The idea behind example 1 is that there is an underlying function f which relates LOSTEALRAT to LOGGED and VIO, or LOSTEALRAT = f(LOGGED, VIO). Since we do not know the functional form of f (e.g., LOSTEALRAT = −2.62 + (.0053)LOGGED + (.0011)VIO), example 1 illustrates how LOSTEALRAT* can be bounded using only our intuition that f produces larger values when both LOGGED and VIO increase.

We formalize example 1 as follows. We assume that f is a monotone function. Let δ_j indicate the directional effect of x_j on $f(X)$, or

$$\delta_j = \text{sign of } \frac{\partial f}{\partial x_j}$$

Let $\Delta = (\delta_1, \ldots, \delta_J)$. We **denote a monotone relationship by** $y(\delta_1 x_1, \ldots, \delta_J x_J) = y(\Delta X)$. For example, MR1 is denoted by LOSTEALRAT(+LOGGED, +VIO), where LOSTEALRAT = y, LOGGED = x_1, VIO = x_2, and $\delta_1 = \delta_2 = +1$.

FIG. 4: RELATIONSHIP AMONG DEPENDENT VARIABLES IN VMSYS1
(EACH POINT IS A 15 MINUTE INTERVAL)



The approach in example 1 is based on the following observation about monotone functions. Given a monotone function f, $X_1 = (x_{11}, \ldots, x_{1J})$, and $X_2 = (x_{21}, \ldots, x_{2J})$, then $f(X_1) \leq f(X_2)$ if X_1 has a smaller value for each x_j which increases with f and a larger value for each x_j which decreases with f. Thus, we can use f to impose a **partial order** ($\prec_f$):

$X_1 \prec_f X_2 \Leftrightarrow$ for all j, $\delta_j x_{1j} < \delta_j x_{2j}$

$X_1 \prec_f X_2$ implies $f(X_1) \leq f(X_2)$

We emphasize that $\prec_f$ is a partial order; so, not all X_1 and X_2 can be compared. Specifically, **X_1 and X_2 are comparable** if either $X_1 \prec_f X_2$ or $X_2 \prec_f X_1$. In example 1, $X_1 = (482, 486)$ and $X_2 = (510, 611)$ are comparable since $(+1)482 < (+1)510$ and $(+1)486 < (+1)611$, so $X_1 \prec_f X_2$. Furthermore if $X_1 \prec_f X_2$, we say that **(y_1, X_1) and (y_2, X_2) agree with $y(\Delta X)$** if $y_1 \leq y_2$.

Now we can state the general approach suggested by example 1. Suppose we want to bound y^* when the independent variables take on the values X^*. If all pairs of measurement instances agree with $y(\Delta X)$, an excellent lower bound is $\max\{y_l \mid X_l \prec_f X^*\}$ and an excellent upper bound is $\min\{y_h \mid X^* \prec_f X_h\}$.

By itself, the foregoing is inadequate because it does not handle those cases in which comparable X's do not agree with $y(\Delta X)$. We handle this by adding an error term to account for deviations from the monotone relationship.

$$y_i = f(X_i) + \varepsilon_i \qquad (3)$$

Where:

f = monotone function with known directional effects

$\varepsilon_1, \ldots, \varepsilon_I$ = error terms which are independent and identically distributed random variables

Thus if $\varepsilon_i = 0$, the aforementioned procedure is reasonable.

We note that equation (3) has the same form as the regression equation in (2). However, NIMF generalizes on regression in two ways. First, NIMF does not assume a known functional form for f; instead, NIMF only requires knowing the directional effect on y (through f) of increasing x_j (as indicated by δ_j). Secondly, the error terms need not be normally distributed; in fact, NIMF makes no distributional assumptions, so it is a non-parameteric technique. Further, NIMF is fairly robust to violations of these assumptions in that they need hold only for X close to X^*.

To summarize,

Obtaining Prediction Intervals Using NIMF

Given

$y_1, \ldots, y_I$ = dependent variables with $y_I = f(X_I) + \varepsilon_I$

$X_1, \ldots, X_I$ = vectors of independent variables with $X_I = (x_{I1}, \ldots, x_{IJ})$

f = monotone function for which the directional effect of increasing each x_j is known

$\varepsilon_1, \ldots, \varepsilon_I$ = error terms which are independent and identically distributed random variables

$1 - \alpha$ = confidence level

X^* = values of independent variables for an unknown y^*

Find

y_L and y_H such that $Pr[y_L \leq y^* \leq y_H] \geq 1 - \alpha$.

Section 4.1 describes the NIMF technique, and appendix B presents a proof that NIMF constructs valid prediction intervals. Section 4.2 shows how the quality of a NIMF model can be evaluated in a manner similar to how R^2 is used for regression models.

4.1 NIMF Technique

NIMF is a two-step technique with an optional third step. The first step selects a **set of potential lower bounds (S_L)** and a **set of potential upper bounds (S_H)** based on the partial order imposed by f. Specifically, in order for y_l to be in S_L, $X_l \prec_f X^*$; similarly, for y_h to be in S_H, $X^* \prec_f X_h$. This ensures that $f(X_l) \leq f(X^*) \leq f(X_h)$; however, it does not guarantee that $y_l \leq y^* \leq y_h$ since we do not know the values of the error terms in equation (3). Step 2 addresses this issue by employing a non-parametric statistical technique to select a member of S_L as a lower bound for y^* and a member of S_H as an upper bound for y^*. An optional third step ensures that the resulting bounds are consistent with the monotone relationship; this is useful for explaining predictions in terms of the monotone relationship and also provides a form of error checking. (See Fig. 5 for a summary of these steps.)

The 3 steps in the NIMF technique are described below. This description is aided by a continuing example in which the following are given:

Continuing Example for Section 4.1

Bound the unknown y^* based on the following

$y(\Delta X)$ = LOSTEALRAT(+LOGGED, +VIO)
$1-\alpha$ = 75%
X^* = (500, 500)

Table 1: Base Measurement Data for Section 4.1 Continuing Example

Entry #	LOGGED (x_1)	VIO (x_2)	LOSTEALRAT (y)
1	510	320	.5
2	450	680	.4
3	490	720	.7
4	391	350	0
5	457	491	.2
6	466	407	0
7	400	400	.1
8	482	486	.3
9	492	492	.6
10	451	465	1.2
11	509	500	.4
12	530	502	.5
13	531	600	.7
14	510	611	1.5
15	558	522	1.1
16	526	544	1.6
17	524	534	1.4

Step 1: Select the Possible-bounds Sets

We want to pick S_L, a set of potential lower bounds for y^*, and S_H, a set of potential upper bounds for y^*. We can do this by using the partial order imposed by f ($\prec_f$). Specifically, if $X \prec_f X^*$, then $f(X) \leq f(X^*)$. (Of course, we are not assured that $y \leq y^*$ since it may be that $\varepsilon >> \varepsilon^*$.) Let $\mathbf{S}_L^0 = \{y_l \mid X_l \prec_f X^*\}$. We require that $S_L \subseteq S_L^0$. Similarly, $\mathbf{S}_H^0 = \{y_h \mid X^* \prec_f X_h\}$, and $S_H \subseteq S_H^0$.

In our continuing example, $S_L^0 = \{y \mid (y,X)$ in Table 1 , LOGGED < 500, VIO $< 500\}$ and $S_H^0 = \{y \mid (y,X)$ in Table 1 , LOGGED > 500, VIO $> 500\}$, which results in:

S_L^0 :	0	.2	0	.1	.3	.6	1.2
S_H^0 :	.5	.7	1.5	1.1	1.6	1.4	

(Note that entry 11 is not included because $VIO_{11} = 500$.)

How should we choose S_L and S_H? We could let $S_L = S_L^0$ and $S_H = S_H^0$. However, if S_L^0 or S_H^0 contain X very distant from X^*, then $|f(X) - f(X^*)|$ will be large and hence the prediction interval will be wide. This motivates making S_L and S_H as small as possible. However, these sets should not be too small since doing so will make NIMF more sensitive to large values of $|\varepsilon|$ (i.e., outliers) which would again widen the prediction interval. We define M as the maximum size of the potential bounds sets, and for simplicity we require that $size(S_L) = size(S_H)$. We define the size of S_L and S_H to be N, where $N = \min\{M, size(S_L^0), size(S_H^0)\}$. Our studies suggest that $10 \leq M \leq 20$ works well.

If the size of S_L^0 exceeds N, we must remove elements from S_L^0 to construct S_L, and similarly for constructing S_H from S_H^0. How should we choose which elements to remove? To minimize $|f(X) - f(X^*)|$, we keep those elements which are closest to X^*. We define distance as

$$d(X_1, X_2) = \left(\sum_{j=1}^{J} \frac{(x_{1j} - x_{2j})^2}{s_j^2} \right)^{\frac{1}{2}} \tag{4}$$

Where:

s_j^2 = standard deviation of x_j

Then,

$$S_L = \{y_l \in S_L^0 \text{ with the } N \text{ smallest } d(X_l, X^*)\} \tag{5a}$$

$$S_H = \{y_h \in S_H^0 \text{ with the } N \text{ smallest } d(X_h, X^*)\} \tag{5b}$$

In our continuing example, $N = 6$. Since $size(S_L^0) = 7 > 6$, we must delete one element from S_L^0 to form S_L. The element of S_L^0 with the largest $d(X, X^*)$ is entry 4 in Table 1. So,

S_L :	.2	0	.1	.3	.6	1.2
S_H :	.5	.7	1.5	1.1	1.6	1.4

Fig. 5: Summary of NIMF

Problem Statement

Given

$y_1, \ldots, y_I$ = dependent variables with $y_i = f(X_i) + \varepsilon_i$
$X_1, \ldots, X_I$ = vectors of independent variables with $X_i = (x_{i1}, \ldots, x_{iJ})$
f = monotone function for which directional effect of increasing x_j is known
$\varepsilon_1, \ldots, \varepsilon_I$ = error terms which are independent and identically distributed random variables
$1-\alpha$ = confidence level
X^* = values of independent variables for y^*

Find

y_L and y_H such that $Pr[y_L \leq y^* \leq y_H] \geq 1 - \alpha$.

Step 1: Select the Potential-bounds Sets

$S_L = \{y_l \in S_L^0$ with the N smallest $d(X, X^*)\}$
$S_H = \{y_h \in S_H^0$ with the N smallest $d(X, X^*)\}$

Where:

$S_L^0 = \{y_l \mid X_l \prec_f X^*\}$
$S_H^0 = \{y_h \mid X^* \prec_f X_h\}$
$\prec_f$ = partial order imposed by f

$$d(X_1, X_2) = \left(\sum_{j=1}^{J} \frac{(x_{1j} - x_{2j})^2}{s_j^2} \right)^{\frac{1}{2}}$$

s_j^2 = standard deviation of x_j
$N = \min[M, size(S_L^0), size(S_H^0)]$
M = maximum size for S_L and S_H

Step 2: Form An Initial Prediction Interval

1. Sort S_L yielding $y_{l,1} \leq y_{l,2} \leq \cdots \leq y_{l,N}$
   Sort S_H yielding $y_{h,1} \leq y_{h,2} \leq \cdots \leq y_{h,N}$
2. $k = \max\left\{ m \text{ such that } \sum_{n=m}^{N} \binom{N}{n} .5^N \geq 1 - \frac{\alpha}{2} \right\}$
3. $y_L = \min\{y_{l,k}, y_{h,N-k+1}\}$
   $y_H = \max\{y_{l,k}, y_{h,N-k+1}\}$

Step 3 (optional): Find Bounds Consistent with the Monotone Function

$y_L^a = y_L$ from step 2, and $y_H^a = y_H$ from step 2.

$$y_L = \begin{cases} -\infty & \text{if } y_L^a < \min S_L \\ \max\limits_{y_l \in S_L} \{y_l \leq y_L^a\} & \text{otherwise} \end{cases}$$

$$y_H = \begin{cases} +\infty & \text{if } y_H^a > \max S_H \\ \min\limits_{y_h \in S_H} \{y_h \geq y_H^a\} & \text{otherwise} \end{cases}$$

Step 2: Form An Initial Prediction Interval

We obtain a prediction interval for y^* by applying a nonparametric statistical technique. We first sort S_L and re-index its elements so that $y_{l,1} \leq \cdots \leq y_{l,N}$. Similarly, S_H is sorted and re-indexed so that $y_{h,1} \leq \cdots \leq y_{h,N}$. Doing so in our continuing example, results in the following:

Index:	1	2	3	4	5	6
S_L :	0	.1	.2	.3	.6	1.2
S_H :	.5	.7	1.1	1.4	1.5	1.6

A $1-\alpha$ prediction interval can then be obtained by selecting a lower bound from S_L and an upper bound from S_H using a variation on a technique for obtaining confidence intervals for the median of a distribution [Bradley 68]. Our technique computes an index k so that $y_{l,k}$ will be the lower bound and $y_{h,N-k+1}$ will be the upper bound. The index is computed as follows:

$$k = \max\left\{ m \text{ such that } \sum_{n=m}^{N} \binom{N}{n} .5^N \geq 1 - \frac{\alpha}{2} \right\}$$

For those cases where there is no such k, $y_L = -\infty$ and $y_H = +\infty$. Referring to our continuing example, $N = 6$ and $1 - \frac{\alpha}{2} = .88$

$$\sum_{n=1}^{6} \binom{6}{n} .5^6 = .98 > .88 \qquad (m = 1)$$

$$\sum_{n=2}^{6} \binom{6}{n} .5^6 = .89 > .88 \qquad (m = 2)$$

$$\sum_{n=3}^{6} \binom{6}{n} .5^6 = .64 < .88 \qquad (m = 3)$$

So, $k = \max\{1, 2\} = 2$ and $N - k + 1 = 5$. Thus, $Pr[.1 = y_{l,2} \le y^* \le y_{h,5} = 1.5] \ge .75$.

In general, we are not assured that $y_{l,k} \le y_{h,N-k+1}$. Thus, we define the prediction interval bounds as follows:

$$y_L = \min\{y_{l,k},\ y_{h,N-k+1}\} \tag{6a}$$

$$y_H = \max\{y_{l,k},\ y_{h,N-k+1}\} \tag{6b}$$

In our continuing example,

$$y_L = \min\{y_{1,2},\ y_{h,5}\} = .1$$

$$y_H = \max\{y_{1,2},\ y_{h,5}\} = 1.5$$

Step 3 (Optional): Find Bounds Consistent with the Monotone Relationship

While step 2 produces a prediction interval, we may want to ensure that the prediction interval is consistent with the monotone relationship in the sense that $y_L \in S_L$ and $y_H \in S_H$. This is desirable for two reasons. First, it makes explaining the predictions much easier. For instance, we can explain the lower bound in our continuing example as follows:

> Entry 7 in table 1 (i.e., $\text{LOSTEALRAT}_7 = .1$) is a lower bound for LOSTEALRAT^* since:
>
> 1. LOSTEALRAT increases with LOGGED and VIO and
> 2. $\text{LOGGED}_7 = 400 < 500 = \text{LOGGED}^*$ and $\text{VIO}_7 = 400 < 500 = \text{VIO}^*$

Secondly, a form of error checking is provided for those cases in which $y_L < \min S_L$ or $y_H > \max S_H$. Such situations indicate a potential violation of the monotone relationship which can impair the accuracy of the predictions. Under such circumstances, it is better to give no bound (i.e., ∞) rather than one based on a faulty assumption.

Let y_L^a be y_L from step 2, and y_H^a be y_H from step 2. To ensure bounds consistent with the monotone relationship, step 3 chooses y_L to be the largest member of S_L such that $y_l \le y_L^a$. Similarly, y_H is the smallest member of S_H such that $y_h \ge y_H^a$. Note that the confidence level remains at least $1 - \alpha$, although the width of the prediction interval may increase. More formally,

$$y_L = \begin{cases} -\infty & \text{if } y_L^a < \min S_L \\ \max\limits_{y_l \in S_L} \{y_l \le y_L^a\} & \text{otherwise} \end{cases} \tag{7a}$$

$$y_H = \begin{cases} +\infty & \text{if } y_H^a > \max S_H \\ \min\limits_{y_h \in S_H} \{y_h \ge y_H^a\} & \text{otherwise} \end{cases} \tag{7b}$$

In our continuing example, we have

$$y_L = \max_{y_1 \in S_L} \{y_1 \le y_{1,2} = .1\} = .1$$

$$y_H = \min_{y_h \in S_H} \{y_h \ge y_{h,5} = 1.5\} = 1.5$$

4.2 Evaluating A NIMF Model

A NIMF model is simply a monotone relationship denoted by $y(\Delta X)$ which specifies a set of independent variables (X) and the directional effect on the dependent variable (y) when an independent variable increases. The accuracy of NIMF predictions can be strongly affected by the degree to which $y(\Delta X)$ holds. Here we present a simple metric, **A**, which assesses the degree to which $y(\Delta X)$ holds for a specific set of measurement data.

One approach to assessing $y(\Delta X)$ is to look at the **fraction of comparable measurement-pairs which agree with** $y(\Delta X)$ (denoted by F_A). That is, given pairs of measurement instances of the form $((y_1, X_1), (y_2, X_2))$ with $X_1 <_r X_2$, for how many such pairs is it true that $y_1 \le y_2$? While F_A has much appeal, it is a little deceiving since we expect some level of agreement just due to chance. Intuitively, we expect that for an arbitrarily selected monotone relationship, a comparable measurement-pair will be equally as likely to agree with the monotone relationship as to disagree with it. So, we assess $y(\Delta X)$ by the increase in agreement compared to what we expect due to chance. Or,

$$A = \frac{F_A - .5}{.5} \tag{8}$$

Where:
- A = increase in agreement compared to chance
- F_A = fraction of comparable measurement-pairs which agree with $y(\Delta X)$

In essence, A assesses how well $y(\Delta X)$ explains the measurement data. If agreement is purely due to chance, $A = 0$. If 100% of the measurement-pairs agree with $y(\Delta X)$, then $F_A = 1$, so $A = 1$. We have found A to be an effective way of evaluating NIMF models.

5. Case Studies

This section compares the accuracy of several least squares regression models to the accuracy of NIMF for predicting contention for the first 16 megabytes of storage in three VM SP/HPO 4.2 systems. (See Fig. 1 for a description of these systems.) Regression and NIMF are compared using the same base measurement data and the same independent variables (i.e., LOGGED and VIO). Models are compared in two ways:

1. Self-evaluation
   How well does the model explain the base measurement data (e.g., R^2 for regression and A for NIMF)?
2. Cross validation
   How accurately can the model predict **cross validation data** (measurements not present in the base measurement data)? There are two criteria:
   a. the **empirical confidence level** which is the fraction of the prediction intervals which contain the actual value (from the cross-validation data)
   b. the average prediction interval width.

For item 1, we want large values for R^2 and A. Item 2 specifies two criteria which we combine into a single goal: minimize the average prediction interval width subject to the constraint that the empirical confidence level is at least $1 - \alpha$. Herein, $1 - \alpha = .75$, so we want the empirical confidence level to be at least 75%.

Throughout these studies, we set M, the maximum size of S_L and S_H, to 20 and use the NIMF model below:

$$y(+\text{LOGGED}, +\text{VIO}) \tag{9}$$

Where:
$y \in \{\text{LOSTEALRAT, FREXTND, PRIMEUTIL}\}$
Also, we use step 3 of the NIMF procedure to obtain bounds consistent with the monotone relationship; so the NIMF prediction intervals tend to be wider than if step 3 is not used.

The choice of the regression model is more difficult because we have little intuition about the algebraic relationship between the independent and dependent variables. So, we take the same approach as in section 3. (See R1, R2, and R3 where y may be LOSTEALRAT, FREXTND, or PRIMEUTIL.) We consider polynomials of increasingly higher degree until either: (a) there is little increase in R^2 or (b) the average width of the regression prediction intervals is smaller than the average width of the NIMF prediction interval.

We begin with LOSTEALRAT in VMSYS1. Recall from section 3 that R3 produces the best R^2 (.37). Fig. 6a shows the regression prediction intervals and the cross validation data for a 75% confidence level. The empirical confidence level is certainly adequate - 94%. However, the average width of the prediction intervals is 1.25, which seems fairly wide. Indeed, in several cases the R3 prediction interval includes negative values, which is unreasonable since LOSTEALRAT is a rate.

Fig. 6b plots 75% NIMF prediction intervals for the same VMSYS1 base measurement data and cross validation data. Again the empirical confidence level (83%) is acceptable. Furthermore, the average prediction interval width is .54 which is 57% smaller than the R3 prediction interval. Also note that the prediction intervals do not contain negative values. Indeed, NIMF always produces prediction intervals with feasible values for the bounds since NIMF uses actual measurement data for the bounds.

Fig. 6: Regression vs. NIMF for VMSYS1 LOSTEALRAT
y = LOSTEALRAT, L = LOGGED, V = VIO
PI = prediction interval

Fig. 6a: Regression Model

$$y = b_0 + b_1L + b_2V + b_3L^2 + b_4LV + b_5V^2 + b_6L^3 + b_7L^2V + b_8LV^2 + b_9V^3 + \varepsilon$$

75% PI % in PI = 94 Avg. Width = 1.25 R^2 = .37

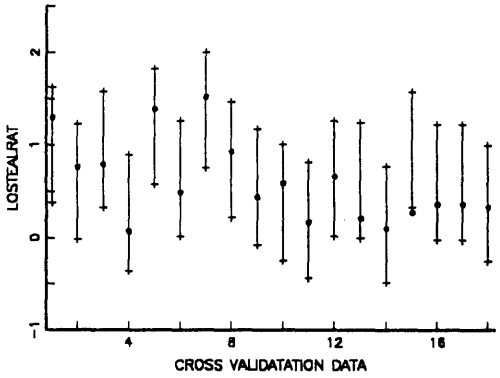


Fig. 6b: NIMF Model

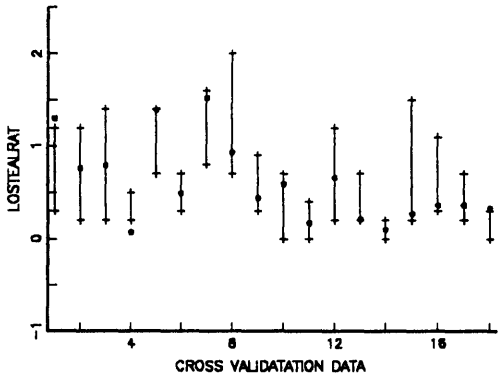
$y(+L, +V)$

75% PI % in PI = 83 Avg. Width = .54 A = .58



Why does NIMF produce prediction intervals which are so much narrower than R3? One explanation is that R3 is probably a poor approximation to the 'true' function relating LOGGED and VIO to LOSTEALRAT. Such a situation results in equational bias which makes the error terms in the regression equation larger and thereby causes wider prediction intervals. Since NIMF does not rely on an explicit form for the function relating LOGGED and VIO to LOSTEALRAT, NIMF does not suffer from equational bias.

Another explanation relates to the nature of the VMSYS1 base measurement data. Recall that regression assumes that the dependent variable has a constant variance over the entire range of independent variables; regression prediction intervals are not very robust to violations of this assumption. Note that the variance of LOSTEALRAT in VMSYS1 increases with LOGGED and VIO. Thus, the overall standard error is too large for small values of LOGGED and VIO, and the cross validation data are mostly in this range; a large standard error creates a wide prediction interval. While NIMF also assumes a constant variance (i.e., the error terms are identically distributed), NIMF is robust to violations of this assumption since it need only hold locally around y^*. That is, NIMF looks at the local behavior around y^* by using the monotone relationship to select a set of potential lower bounds (S_L) and potential upper bounds (S_H). So, the assumption of constant variance need only hold within $S_L \cup S_H$. Thus, when the variability within $S_L \cup S_H$ is small, NIMF produces narrower prediction intervals than when the variability within $S_L \cup S_H$ is large.

The preceding study is somewhat of a worst case for regression. How does NIMF compare to regression when regression should do well? The LOSTEALRAT data for VMSYS3 offer an opportunity to answer this question. From Fig. 7, we see that LOSTEALRAT is almost linear in VIO with a somewhat smaller effect due to LOGGED. As before, NIMF, R1, R2, and R3 are used to construct prediction intervals for the cross-validation data. These results are the first set of entries in Fig. 8. In all cases, the empirical confidence level is acceptable. Also, NIMF produces smaller prediction intervals than both R1 and R2. Although NIMF produces wider prediction intervals than R3, they are only 8% wider. Thus, even in a case where regression should do well NIMF is still competitive.

Fig. 8 summaries all of the case studies. Note that for the PRIMEUTIL study on VMSYS1, there is one cross-validation point for which NIMF does not produce bounds. The reason for this is that the monotone relationship does not hold near that X^*, and so step 3 of NIMF sets the bounds to ∞.

We now review all five case studies summarized in Fig. 8. Note that with the exception of R3 for VMSYS3, NIMF produces narrower prediction intervals than all three regression models while still ensuring an acceptable empirical confidence level. It is possible that with additional effort better regression models could be obtained. However, for relatively little effort, NIMF produces surprisingly accurate predictions.

6. Evaluation of NIMF

A predictive model can greatly assist with workload management by anticipating the impact of increasing or decreasing workload. Such a model should have two characteristics:

1. Accuracy
   a. For a $1-\alpha$ prediction interval (e.g., 75%), the empirical confidence level (i.e., the fraction of the actual values which lie within their prediction interval) should be at least $1-\alpha$.
   b. The prediction intervals should be narrow.
2. Ease of model formulation

Ease of model formulation is desirable since resource constraints may be installation specific (e.g., an installation-developed service machine). Thus, if a predictive model is to be used, it must be developed by the installation's performance analysts. Since performance analysts often have many other system programming responsibilities, model construction has to be fast and effective.

NIMF offers advantages in both accuracy and ease of model formulation. The case studies suggest that **NIMF is as accurate as a good regression model.** Specifically, in four of the five case studies, NIMF produces prediction intervals which are 30% to 57% narrower than our best regression model; in the fifth case, the NIMF prediction interval is only 8% wider than that which our best regression model produces. In all cases, the NIMF empirical confidence level is acceptable.

Another aspect of NIMF's accuracy is that its choice of prediction interval bounds tends to be more meaningful than simplistic regression models. For example, all three regression models produce

FIG. 7: LOSTEALRAT VS. INDEPENDENT VARIABLES FOR VMSYS3
(EACH POINT IS A 15 MINUTE INTERVAL)

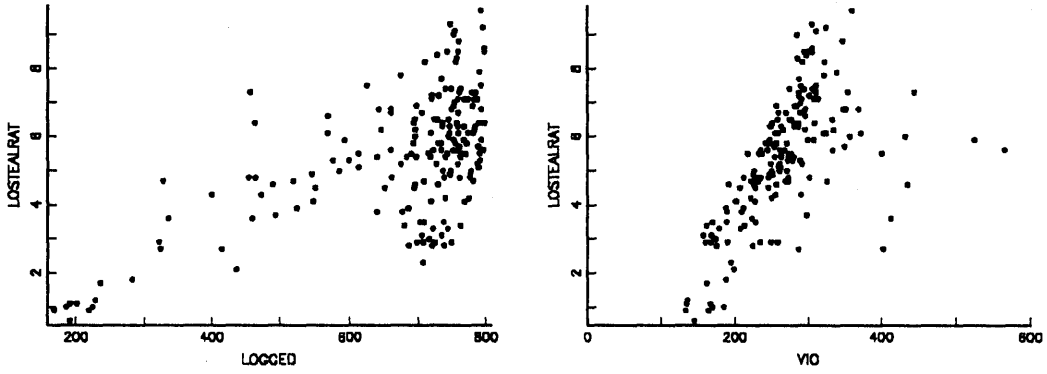


Fig. 8: Summary of Comparisons Between NIMF and Regression Cross Validation Data with 75% Prediction Intervals

System	Dependent Variable	Method	Self-Eval	% in PI	% Chg. in PI Width Compared to NIMF

		R3	$R^2 = .37$	94	131
VMSYS1	FREXTND	NIMF	$\Lambda = .80$	88	
		R1	$R^2 = .32$	88	100
		R2	$R^2 = .44$	94	82
		R3	$R^2 = .45$	94	82
VMSYS1	PRIMEUTIL	NIMF*	$\Lambda = .38$	83	
		R1	$R^2 = .073$	100	49
		R2	$R^2 = .11$	100	46
		R3	$R^2 = .16$	100	43
VMSYS2	FREXTND	NIMF	$\Lambda = .58$	75	
		R1	$R^2 = .21$	100	58
		R2	$R^2 = .22$	100	58

* One NIMF point for prime utilization had no lower bound
PI = prediction interval

prediction intervals with negative values for the low-DPA page steal rate and free storage extend rate; NIMF never does. This characteristic results from NIMF choosing the prediction interval bounds from measurement data. Thus, **NIMF prediction interval bounds will always be feasible values of the dependent variable** since the bounds are taken from actual measurement data.

A further consideration relating to accuracy is robustness to outliers. Since least squares regression is a global technique (i.e., all of the base measurement data are used to construct each prediction interval), a few outliers can greatly affect all of the predictions. In fact, an important part of building a regression model is identifying outliers and removing their effects [Daniel and Wood 80]. On the other hand, NIMF is relatively insensitive to outliers since NIMF's assumptions need only hold locally around y^*. This results from NIMF selecting prediction interval bounds based on the potential-bound sets S_L and S_H. Specifically, consider the case where $size(S_L) = size(S_H) = 20$. A prediction interval for y^* is affected only by an outlier which is one of the 20 closest points less than X^* or one of the 20 closest points greater than X^*. If we further assume a 75% confidence level, then the (initial) prediction interval bounds will be the seventh smallest element in S_L and the seventh largest element in S_H. Thus, there would have to be at least seven outliers in S_L or in S_H in order for the prediction interval to be seriously affected.

NIMF also has significant advantages for model formulation. Formulating a NIMF model only requires specifying a monotone relationship between the independent and dependent variables. In contrast, least squares regression requires specifying an algebraic relationship. Finding a good algebraic relationship can be extremely difficult, as indicated by our attempts in section 3 to construct a regression model for the low-DPA page steal rate and by the case studies in section 5. In theory, a polynomial can approximate any 'smooth' function. Indeed, our approach to the regression models has been to use polynomials of increasingly higher degree. However, our experience indicates that much more sophistication is required. Instead of trying to find a good algebraic expression relating contention for the first 16 megabytes of storage to workload variables, we use NIMF to exploit a fairly obvious monotone relationship - contention for the first 16 megabytes of storage should increase with workload. Our experience has been that **NIMF can make model formulation trivial.**

NIMF does have two shortcomings. First, unlike regression, NIMF is inherently an interpolative technique. Thus, predictions can be made only in variable regions where there are measurement data. For workload management, this may not be a severe drawback since installations routinely collect large volumes of measurement data over a wide range of variable values.

A second issue with NIMF arises from its requiring a monotone relationship between dependent and independent variables. While monotone relationships are quite general and are easy to state, not all functions are monotone. One technique for handling non-monotone functions is to partition them into several monotone sub-functions. We are currently pursuing this idea.

An additional consideration when using NIMF is that its CPU requirements can be greater than those for regression. In regression, all of the base measurement data are examined when fitting the regression equation. However, each prediction only requires a few algebraic operations. For example in regression model R1, each point estimate requires 2 multiplications and 2 additions. On the other hand, NIMF examines all of the base measurement data for each prediction (so as to compute the potential-bounds sets). We have used NIMF with base measurement data ranging in size from 100 to 500 entries and have consistently obtained execution times for NIMF which are comparable to those for regression. However, NIMF's processing requirements may become an issue if more base measurement data are used.

Our overall feeling is that NIMF is a useful technique if sufficient data are present and monotonicity is a reasonable assumption. Indeed, our experience with NIMF extends beyond predicting contention for the first 16 megabytes of storage in VM SP/HPO. We have used NIMF to develop high-level models for a variety of MVS subcomponents (e.g., the input/output supervisor and the auxiliary storage manager). As with contention for the first 16 megabytes of storage in VM SP/HPO, we have found these models easy to formulate and their accuracy to be comparable to a good regression model.

7. Application of NIMF to Workload Management

Two questions asked in workload management are:

1. How much can workload be increased before resource utilizations are excessive?
2. How much must workload be decreased to obtain acceptable resource utilizations?

An effective way to answer these questions is to use a predictive model to plot the percentage change in workload against measures of resource contention. This section uses the NIMF model LOSTEALRAT(+LOGGED, +VIO) to explore the effect on the VMSYS1 low-DPA page steal rate (LOSTEALRAT) when we vary the number of logged-on users (LOGGED) and the total virtual machine VIO rate (VIO).

In the base measurement data for VMSYS1, the average value of LOGGED is 500 and for VIO is 500. We take these values as the initial workload; that is, the workload values for a 0% change are LOGGED = 500 and VIO = 500. Similarly, a 10% increase in total workload results in LOGGED = 550 and VIO = 550. We also consider the impact of only changing LOGGED while VIO = 500 and only changing VIO while LOGGED = 500.

Fig. 9 plots the results. Note that when both LOGGED and VIO increase, LOSTEALRAT grows quickly. Indeed, a 12% increase in both workload variables results in a low-DPA page steal rate between .8 and 1.6, which might be of concern [Hoag 86] Given the plots in Fig. 9, what can be done? One possibility arises from observing that LOGGED has a much greater impact on LOSTEALRAT than does VIO. Furthermore, in VMSYS1 a large fraction of the logged-on users are idle for an extended period of time. This suggests that LOSTEALRAT might be controlled by logging-off such users. Of course the benefits of doing so must be weighed against the inconvenience caused to users.

8. Conclusions

Workload management can be made easier by being able to predict resource contention from workload variables. In large VM SP/HPO systems, contention for the first 16 megabytes of storage is a major performance concern. Since we know of no existing model to predict this type of storage contention, we have attempted to develop such a model.

Our attempts to use least squares regression met with little success because regression requires us to provide something that we do not know - an algebraic expression relating workload to contention for the first 16 megabytes of storage. However, the regression studies do suggest that contention for the first 16 megabytes of storage is monotonically increasing in the workload variables.

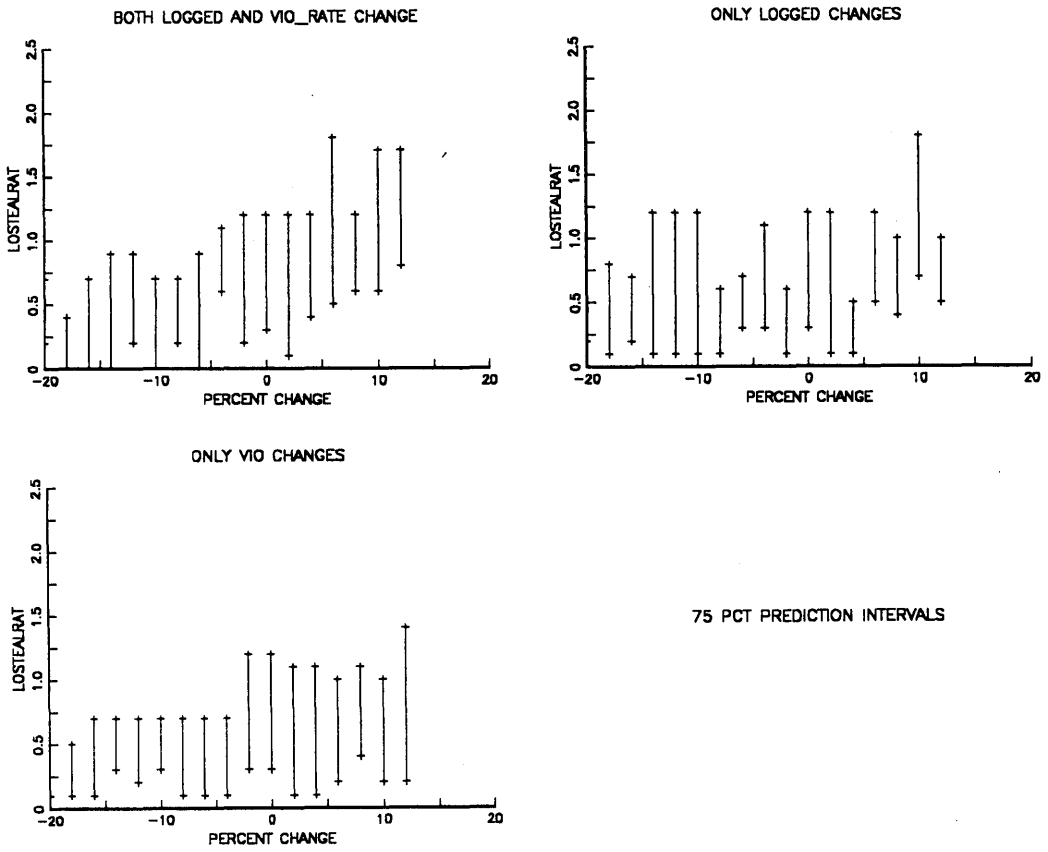
This observation has motivated the development of an apparently new technique - non-parameteric interpolative-forecasting for monotone functions (NIMF). NIMF is a generalization of a technique commonly used by performance analysts. A NIMF model is a monotone relationship which specifies the directional effect on the dependent variable (i.e., increases or decreases) when an independent variable increases. NIMF constructs a prediction interval by using the monotone relationship to select the prediction interval's lower and upper bounds from the measurement data.

Our experience suggests that NIMF is accurate and NIMF models are easy to formulate. Case studies of three VM SP/HPO 4.2 systems suggest that NIMF is as accurate as a good regression model. Specifically, in four of the five case studies, NIMF produces prediction intervals 30% to 57% narrower than the best regression model considered. The fifth case is one in which we expect regression to do well. Even so, NIMF produces narrower prediction intervals than two of the regression models, and NIMF's prediction intervals average only 8% wider than the third regression model. In all cases, the empirical confidence level (i.e., the fraction of the actual values which lie in their prediction interval) equals or exceeds the expected confidence level (i.e., 75%). Additionally, NIMF always selects feasible values for the prediction interval bounds, unlike regression models. For example in the case studies, the regression prediction intervals include negative values for low-DPA page steal rate. Furthermore, NIMF can be made fairly robust to outliers by controlling the maximum size of the potential-bounds sets.

NIMF facilitates model formulation by only requiring models to specify the directional effect on the dependent variable when an independent variable increases. In the case of contention for the first 16 megabytes of storage, this has tremendous advantages since we have little intuition about its algebraic relationship to workload.

NIMF has two limitations: (1) it is inherently an interpolative technique, and (2) the function relating the independent variables to the dependent variable must be monotone. The former may not be a problem for workload management since installations routinely collect large volumes of measurement data over a wide range of variable values. The latter can be a more serious limitation; however, when monotonicity is a reasonable assumption, NIMF can be a

Fig. 9: NIMF Predictions of Effect of Workload Changes in VMSYS1



powerful technique. An additional consideration when using NIMF is that it can impose greater processing requirements than regression; however, we have not found NIMF's processing requirements to be excessive.

Although our experience with NIMF is limited, we feel that it can be an important tool for managing computer performance. For example, we proposed a strategy for controlling low-DPA page steals in a large VM SP/HPO system by using NIMF to predict the effect of workload changes on contention for the first 16 megabytes of storage. More generally, performance management often requires considering installation-specific resource constraints (e.g., an installation-developed service machines) which are difficult to take into account in pre-packaged models. One could construct a queueing or regression model, but these techniques require specifying algebraic relationships which may be non-trivial to discover. NIMF offers an appealing alternative since one need only specify directional effects rather than algebraic relationships.

Appendix A: List of Symbols

Λ = fractional increase in agreement with the monotone relationship compared to that expected due to chance; assesses how well a monotone relationship fits the data
$1 - \alpha$ = confidence level for a prediction interval
$d(X_1, X_2)$ = distance between X_1 and X_2
δ_j = directional effect of j-th independent variable; $\delta_j \in \{1, -1\}$
$\Delta = (\delta_1, \ldots, \delta_J)$
$\frac{\partial f}{\partial x_j}$ = first derivative of f with respect to x_j (i.e., directional effect on f of increasing x_j).
h = index of element in S_H or $S_H^{\wp}$
i = index used for measurement instances (observations)
I = number of measurement instances (observations)
j = index used for independent variables
J = number of independent variables
k = index of bounds obtained in step 2 of NIMF
l = index of element in S_L or $S_L^{\wp}$
N = maximum size of a potential bound set
$Pr[y_L \leq y^* \leq y_H]$ = probability of y^* being between y_L and y_H
$S_H^{\wp}$ = set of all potential upper bounds in S
$S_L^{\wp}$ = set of all potential lower bounds in S
S_H = subset of $S_H^{\wp}$ used to construct prediction interval
S_L = subset of $S_L^{\wp}$ used to construct prediction interval
x_j = j-th independent variable
x_{ij} = value of the j-th independent variable for the i-th measurement instance
X = vector of independent variables, $(x_1, x_2, \ldots, x_J)$
X^* = values of independent variables used to predict an unknown y^*
X_i = vector of values of independent variables for the i-th measurement instance, $(x_{i1}, x_{i2}, \ldots, x_{iJ})$
y = dependent variable
y^* = value of dependent variable associated with the independent variables X^*
y_i = value of the dependent variable for the i-th measurement instance
y_h = element in S_H
$y_{h,k}$ = k-th smallest element in S_H
y_H = upper bound for y^*
$y_H^{\wp}$ = upper bound for y^* produced in NIMF step 2
y_l = element in S_L
$y_{l,k}$ = k-th smallest element in S_L
y_L = lower bound for y^*
$y_L^{\wp}$ = lower bound for y^* produced in NIMF step 2
(y_i, X_i) = measurement instance
$y(\Delta X)$ = monotone relationship between X and y; Δ specifies the directional effect on y of each independent variable in X
$\prec_f$ = partial order imposed by f; $X_1 \prec_f X_2 \Leftrightarrow$ for all j, $\delta_j x_{1j} < \delta_j x_{2j}$

A Simple Linear Programming Model For Computation Center Investment Decisions

Matt J. Merges
AT&T Bell Laboratories

ABSTRACT

Computation center management is often faced with the problem of selecting from a set of technically feasible solutions to satisfy a service requirement. In the ideal case, the decision is based on the net present cost of the alternatives. The major problem involved in this approach is the estimation of the cash flows associated with each option. Future cash flows such as salvage values or technical support costs pose major difficulties. As a result, decisions are often made using uncertain information.

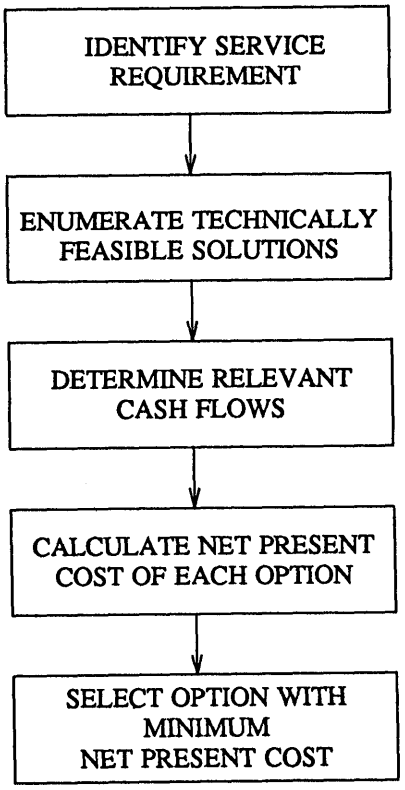
A linear programming model is developed to assist the manager in the decision making process. The model selects the least cost alternative available from the set of technically feasible options. The major advantage of the model over existing decision making tools is the sensitivity analysis that results from the solution of the model. The analysis indicates which financial assumptions are critical to the decision and which assumptions are of minor consequence. This information can then be used to determine the degree of certainty of the decision. It also indicates which assumptions need to be refined if a more certain decision is desired.

1. Introduction

Computation center management is often faced with the problem of deciding among a set of technically feasible options to satisfy a service requirement. An example of such a decision is the choice of a computing system to satisfy a projected customer service demand. Several types of new hardware could probably be acquired to meet the expected demand. Existing systems within the computation center might be vacated and reused. Another possibility is using surplus equipment available from other computation centers within the corporation.

In the ideal case the manager should first enumerate the set of technically feasible solutions. Next for each of these options (s)he should calculate the net present value of the cash flows [1] involved over the expected life of the service requirement. Finally, the manager should select the option which has the minimum net present cash flow. This process is illustrated in Figure 1.

The major financial problem we encounter with this methodology is the estimation of the cash flows associated with each feasible option. Quantities such as salvage values or future maintenance costs are difficult to predict. In addition, usually a large number of cash flows are associated with each option.



IDENTIFY SERVICE REQUIREMENT
ENUMERATE TECHNICALLY FEASIBLE SOLUTIONS
DETERMINE RELEVANT CASH FLOWS
CALCULATE NET PRESENT COST OF EACH OPTION
SELECT OPTION WITH MINIMUM NET PRESENT COST

Figure 1. Standard Decision Process

Cash flow estimation is widely recognized as an imperfect science requiring major effort. Since we are dealing with incomplete information (estimates), we need to establish degrees of criticality[1] for each of our estimates. To know the accuracy of the information is not sufficient. If we know which of our estimates are critical to the decision and which are of minor consequence, we can channel our limited managerial resources correctly. If a particular estimate is shown to be of significant consequence to the decision, then we want to refine the estimate until we reach an appropriate degree of certainty. [2] If, on the other hand, an estimate is shown to be of little consequence to the decision, then we need not expand any additional resources to refine the information. This method of decision making is illustrated in Figure 2.

Consider the following simple example as an illustration. Suppose we make a decision where one of the cash flow estimates is a salvage value of $100,000. If we know that the salvage value estimate could change by $50,000 without affecting the decision, we probably would be satisfied with the $100,000 number. That is, we would be reasonably certain that our decision will remain valid even though there may be fluctuations from our estimate when the decision is executed. If, on the other hand, we know that a $5,000 change would alter our decision, then we may want to refine our estimate of the salvage value depending on our current level of certainty.

The model developed in this paper determines the least cost alternative from a set of technically feasible options and, as part of the solution, automatically provides a sensitivity analysis of the basic financial assumptions. It is the latter information that is the major value of the model. Formulating an acquisition problem in terms of this model will force a manager to identify the basic financial assumptions involved in the decision. It will also provide the manager with the information required to translate these assumptions into cash flows.

The output from the model can be obtained using other methods that employ break-even financial analysis techniques. [3] The advantage of this model is that the output is comprehensive[2] and that the formulation develops understanding of the underlying cash flow aspects of the decision.

1. We need to understand how critical the estimate is to the decision rather than understanding the absolute accuracy of the estimate. If, for example, we overestimate a cash flow by 100% but, because of other more critical factors it doesn't affect the decision, our estimate is satisfactory from the decision task point of view.

2. Some Basic Linear Programming Concepts

The model we develop in this paper is a simple linear programming model. Before we present the derivation of the model, we discuss a few basic linear programming concepts. These concepts prove the correctness of the model and indicate how to use the output of the model for the desired sensitivity analysis. They will also be of value when we describe the process of translating a specific acquisition decision task into the model.

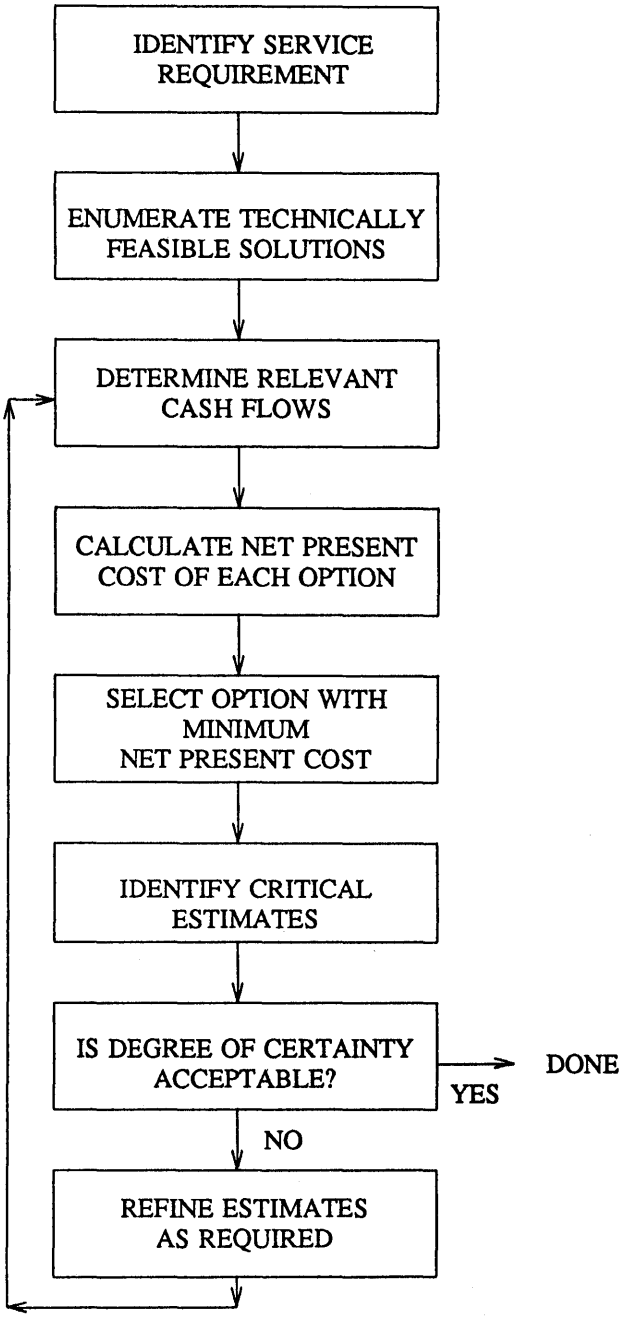


Figure 2. Decision Process with Feedback

2. The model's output automatically provides decision sensitivity information for each of the basic economic assumptions.

2.1 *Format of the Basic Linear Programming Model*

The first concept we introduce is the generic form of the linear programming [4] that is the foundation for our model. We write this linear programming as

$$\textit{minimize} \sum_{i=1}^{m} \sum_{j=1}^{n_i} f_{ij} \times X_{ij} \qquad (2.1)$$

subject to

$$X_{ij} - a_{ij} \times D_i = 0 \qquad \forall\, i \text{ and } \forall\, j \;. \qquad (2.2)$$

In this linear program the objective function, $\sum_{i=1}^{m} \sum_{j=1}^{n_i} f_{ij} \times X_{ij}$, consists of a set of decision variables, $\{X_{ij}\}$, and a set of constants, $\{f_{ij}\}$. These constants are usually called the coefficients of the objective function. The constraints of the program, $\{X_{ij} - a_{ij} \times D_i = 0\}$, introduce an additional set of constants, $\{a_{ij}\}$, and another set of decision variables, $\{D_i\}$.

The two sets of constants are used to define the cost estimates associated with the acquisition decision. They are precisely defined in a section 3 of the paper. The variable sets are used to output the minimum cost option and the sensitivity analysis for the basic estimates.

In this paper, we are not interested in the theory or the techniques that are used to solve linear programming problems. The solution theory is well developed, and many software packages are available for solving the problems. This model generates a very simple class of linear programming problems. They can easily be solved on a desktop computer such as the AT&T PC6300 running the LINDO linear programming package. [5] The examples presented in this paper were solved on a PC6300 with the LINDO system.

2.2 *Stable Coefficient Range*

We will call the set of non zero objective function decision variables that form the solution to one of our linear programming problems the *character* of the solution [6]. That is,

$$X_{ij} \neq 0 \longleftrightarrow X_{ij} \in \textit{character} \;. \qquad (2.3)$$

Now, part of the output from all standard linear programming packages is the range over which a coefficient in the objective function may vary without changing the character of the solution. That is, for each coefficient f_{ij} in the objective function, a range $[L_{ij}, U_{ij}]$ exists such that if f_{ij} is varied unilaterally[3] within this range no change occurs in the character of the solution.

3. Unilaterally in this context means that there are no other changes to the constant sets that define the specific linear programming problem.

This fact is critical to the model's sensitivity analysis. Suppose, for example, that a coefficient in the objective function represents our estimate of the salvage value for a system. The stable range for this coefficient would indicate the range over which the the salvage value could vary without changing the character of the solution. As we see in the following sections the character of the solution will change if and only if our acquisition decision should change. Thus, this range tells us how sensitive our decision is to the estimate of the salvage value.

2.3 *Variable Reduced Cost*

The reduced cost concept applies to objective function decision variables that are not part of the character of the solution. Reduced costs are the amount that the optimum solution would be degraded if a unit of the associated variable is forced into the character. For our model reduced costs are needed to calculate the costs of the options that are not optimum.

3. *Basic Model Formulation*

Computation center management often has multiple options to choose from when deciding how to satisfy a service requirement. For example, if a request is made for a system test machine, they might meet the requirement by acquiring a new system, by using a system scheduled for disposal, or by allocating a portion of an existing system for testing. As we have indicated above, given that each of the options is technically and environmentally feasible, the choice should be based on a present value cost analysis over the expected life of the requirement.

The cost of each option depends on a number of basic cost assumptions. These assumptions usually represent quantities that are not further divisible during the normal decision making process. Examples of these basic assumptions are purchase prices and monthly lease rates for processors. Others include monthly maintenance and environmental costs. Basic cost assumptions can also represent revenue. An example of a revenue assumption is the monies expected for an existing processor when it is used as a trade-in for a newer piece of equipment. We call the basic cost assumptions associated with an option the *cost factors* of the option. We use the notation f_j to denote the jth factor. With this in mind, we can express the cost of an option as a function of its factors. If an option has n factors we write the cost as

$$\textit{Cost} = O(f_1, f_2, \ldots, f_n) \;. \qquad (3.1)$$

where f_j represents the jth cost factor of the option.

To extend this notation to multiple options, we introduce an option index, i, and add this index as a subscript to the notation for cost factors. If option i has n_i cost factors we write the cost as

$$Cost_i = O_i(f_{i1}, f_{i2}, ..., f_{in_i}) . \quad (3.2)$$

The basic assumption of our model is that the actual cost of an option is a linear function of its factors. For example, if a factor, f_{ij}, is the monthly lease rate for a processor, we assume that the total cost contributed by this factor has the form $a \times f_{ij}$, where a is the amount that the factor contributes to the overall cost of the option. For this example, if we are considering a 36-month lease and are assuming an 8% annual cost of money to the corporation, the amount is calculated as

$$a = 1 + \frac{1}{1+.08/12} + \frac{1}{(1+.08/12)^2} \quad (3.3)$$

$$+ \frac{1}{(1+.08/12)^3} + \cdots + \frac{1}{(1+.08/12)^{35}} .$$

We use the notation a_{ij} to denote the amount that the *jth* factor of the *ith* option contributes to the cost of the *ith* option. Thus, the cost of the *ith* option is written as

$$Cost_i = \sum_{j=1}^{n_i} f_{ij} \times a_{ij} . \quad (3.4)$$

Given this notation, a linear programming model for selecting the least cost option from among a set of m options and providing factor sensitivity analysis is

$$minimize \sum_{i=1}^{m} \sum_{j=1}^{n_i} f_{ij} \times X_{ij} \quad (3.5)$$

subject to

$$X_{ij} - a_{ij} \times D_i = 0 \qquad \forall\, i \text{ and } \forall\, j \quad (3.6)$$

$$\sum_{i=1}^{m} D_i = 1 \quad (3.7)$$

$$D_i \geq 0 \qquad \forall\, i . \quad (3.8)$$

It is worthwhile to say at this point that the X_{ij} dimensionless dummy variables are introduced into the formulation of the problem so that the sensitivity analysis will be performed on the basic factors of each option in the decision problem. We want to understand the sensitivity of our decision to the values of f_{ij} but are not particularly interested in the sensitivity to the product $a_{ij} \times f_{ij}$.

4. Correctness of the Model

First, we demonstrate that the model will select the least cost option, from the options described by the two constant sets $\{a_{ij}\}$ and $\{f_{ij}\}$. The selection will be output via the decision variable set $\{D_i\}$. If option l is the least cost option, the variable D_l will have a value of 1 while all other D_is will have a 0 value.

Consider the objective function $\sum_{i=1}^{m} \sum_{j=1}^{n_i} f_{ij} \times X_{ij}$.

By rewriting the constraints

$$X_{ij} - a_{ij} \times D_i = 0 \quad (4.1)$$

as

$$X_{ij} = a_{ij} \times D_i \quad (4.2)$$

and substituting, we can write the objective function as

$$\sum_{i=1}^{m} \sum_{j=1}^{n_i} f_{ij} \times a_{ij} \times D_i . \quad (4.3)$$

Using (3.4), this can be rewritten as

$$\sum_{i=1}^{m} Cost_i \times D_i . \quad (4.4)$$

Now, select l such that

$$Cost_l < Cost_i \qquad \forall\, i \neq l . \quad (4.5)$$

Then for $D_i \geq 0$ we have

$$D_i \times Cost_l < D_i \times Cost_i \qquad \forall\, i \neq l . \quad (4.6)$$

Therefore,

$$\sum_{i=1}^{m} D_i \times Cost_l < \sum_{i=1}^{m} D_i \times Cost_i . \quad (4.7)$$

Factoring, we have

$$Cost_l \times \sum_{i=1}^{m} D_i < \sum_{i=1}^{m} D_i \times Cost_i . \quad (4.8)$$

Since $\sum_{i=1}^{m} D_i = 1$, we obtain

$$Cost_l < \sum_{i=1}^{m} D_i \times Cost_i . \quad (4.9)$$

Now, define the set $\{D'_i\}$ as

$$D'_i = 0 \qquad \forall\, i \neq l \quad (4.10a)$$

$$D'_l = 1 . \quad (4.10b)$$

Since $Cost_l = \sum_{i=1}^{m} D'_i \times Cost_i$, we have from (4.9)

$$\sum_{i=1}^{m} D'_i \times Cost_i < \sum_{i=1}^{m} D_i \times Cost_i . \quad (4.11)$$

Thus, the set $\{D'_i\}$ defines the least cost option and will be output from the model due to the minimization request and the two constraints on the decision variable set $\{D_i\}$.

Next, we demonstrate that the desired factor sensitivity analysis results from the solution of the model. Recall that for each coefficient in the objective function,[4] there exists a range over which the coefficient may vary unilaterally without changing the basis of the solution. In our model, we will use the notation $[L_{ij},U_{ij}]$ to specify the stable range of the coefficient f_{ij}.

Consider the *character* of the solution to our model. By definition of character and using the constraints of our model we have

$$X_{ij} \in character \longleftrightarrow D_i = 1 . \quad (4.12)$$

Likewise, we have

$$X_{ij} \in \overline{character}^{5} \longleftrightarrow D_i = 0 . \quad (4.13)$$

Now, consider a new problem defined by the sets $\{a'_{ij}\}$ and $\{f'_{ij}\}$ where

$$a'_{ij} = a_{ij} \qquad \forall\, i \text{ and } \forall\, j \quad (4.14)$$

and

$$f'_{ij} = f_{ij} \qquad \forall\, i \neq p \text{ and } \forall\, j \neq q \quad (4.15)$$

Let

$$f'_{pq} \in [L_{pq},U_{pq}] . \quad (4.16)$$

Then by definition of stable coefficient range we have

$$X_{ij} = 0 \longleftrightarrow X'_{ij} = 0 \quad (4.17)$$

and

$$X_{ij} \neq 0 \longleftrightarrow X'_{ij} \neq 0 . \quad (4.18)$$

From this, it follows that

$$D_i = 0 \longleftrightarrow D'_i = 0 \quad (4.19)$$

and

$$D_i = 1 \longleftrightarrow D'_i = 1 . \quad (4.20)$$

Thus, if a single cost factor, f_{pq}, varies within its stable coefficient range, the least cost option is the same. This implies that our decision is stable. The range, $[L_{pq},U_{pq}]$, defines the sensitivity of our decision to the basic cost estimate f_{pq}.

Consider the following example. If the factor, f_{ij}, represents the cost of a processor and is \$750,000, and sensitivity analysis states that the stable range for this coefficient is [500000,1000000], then we can conclude that as long as the cost is between \$500,000 and \$1,000,000, our optimum choice does not change. This in effect tells us that our estimate of the cost of the processor is probably not critical to the decision at hand.[6]

Note again, however, that the sensitivity analysis provides for a unilateral study of the cost factors (that is to say that all other factors are assumed constant when one is varied within its stable range).

5. *Repeated Factor Problem*

A problem exists with the sensitivity analysis if a factor is common to more than one option. For example, two options of a decision to purchase a new computer system may involve the trade-in of a particular type of system. The factor would be the actual market sell value, but the amount of the factor in each option could differ, for example, because of different depreciation schedules. This is a typical case where different systems of the identical type were acquired at different times.

The problem with the sensitivity analysis for such a case is that the stable coefficient range presented assumes a unilateral change in the coefficient (factor), market sell value. If the same factor appears in more than one option, then the unilateral analysis fails.

This problem is solved by first observing that the cost of option i, $Cost_i$, is a linear function of any of its factors when the others are held constant. For example, if all factors of option i are held constant except factor j, we can write

$$Cost_i = b_{ij} + a_{ij} \times f_{ij} \quad (5.1)$$

where b_{ij} is a constant with the value

$$b_{ij} = \sum_{i \neq j}^{n_i} a_{ij} \times f_{ij} . \quad (5.2)$$

Suppose that we are deciding between two options, p and q, with cost functions as defined above and common factor f_{pj} and f_{qk}. If we assume that all other factors are constant, we can write the cost functions as

$$Cost_p = b_{pj} + a_{pj} \times f_{pj} \quad (5.3)$$

$$Cost_q = b_{qk} + a_{qk} \times f_{qk} . \quad (5.4)$$

Assume that $Cost_p < Cost_q$.

If $a_{pj} = a_{qk}$, the two lines represented by $Cost_p$ and $Cost_q$ are parallel and there is no break-even point. That is, there is no value of f_{pj} (or f_{qk}) which makes the cost of option q less than the cost of option p.

4. For our model, the coefficients are the cost factors $\{f_{ij}\}$.

5. We use the notation $\overline{character}$ to denote the logical compliment of the *character* with respect to the set $\{X_{ij}\}$.

6. We assume that we can estimate the cost of a processor with an accuracy of at least 33%.

In the case where the two lines are not parallel, the break-even point is the value of f_{pj} where the two cost lines intersect. We can find this value by equating the two functions[7] and solving for f_{pj}. We have

$$f_{pj} = \frac{b_{qk} - b_{pj}}{a_{pj} - a_{qk}} . \quad (5.5)$$

The cost equation constants are calculated as

$$b_{pj} = Cost_p - f_{pj} \times a_{pj} \quad (5.6)$$

and

$$b_{qk} = Cost_q - f_{qk} \times a_{qk} . \quad (5.7)$$

Now $Cost_p$ is output as part of the solution to the linear programming problem. It is the computed minimum value of the linear programming problem.

$Cost_q$ can be calculated from the reduced cost of its factors and the corresponding amounts of its coefficients. The calculation is

$$Cost_q = Cost_p + \sum_{i=1}^{n_q} Reduced\ Cost_{qi} \times a_{qi} . \quad (5.8)$$

The reduced costs are also part of the standard output from linear programming systems.

An alternate method to calculate $Cost_q$ for this case is to artificially force the linear programming to select option q. To do this, set one of the factors of option p to a very high value[8] and rerun the program. The resulting value will then be the value of $Cost_q$.

6. *The Model Is Not a Budget Generation Tool*

The purpose of the linear programming model presented in this paper is to provide a tool for better understanding the effects of assumptions on economic decisions. The specification of the options for evaluation need include only those factors relevant to the decision. For example, if the decision involves the selection of a computing system from a number of alternatives, but each alternative requires the same staff for operation, the cost of staff need not be a factor. This fact is important to point out so that results of the linear programming are interpreted correctly. The value of the linear programming solution is simply a number that gives the cost of the optimum solution relative to the other options. It should not be used to generate budgets.

For the sensitivity analysis, however, the stable ranges presented are in terms of absolute dollars for the associated factors.

7. *A Simple Example*

Suppose that we have identified a service requirement to provide a test system for a four year period. Also assume that we have identified two technically feasible options that will satisfy this requirement. Option 1 is to purchase a new system, system A, and use it exclusively for the test requirement. We assume that system A will be able to provide the required processing power over the four year period. If we exercise this option, we will also dispose of a larger older technology system, system B, that will become available at the start of the study interval.

Option 2 is to provide the test environment on system B. This system is able to provide more processing power than the new test requirement so that we will also be able to move test work from one of our production systems to system B. The former test capacity on the production system can be used to meet an expected increase in demand over the four-year period.

7.1 *Option 1 Factors and Amounts*

A. "Cost of System A (f_{11})"

The first factor for option 1 is the cost of the system. Our estimate of the cost is $735,000. The amount of this factor is the initial cost minus depreciation tax benefits. In present value terms[9] the amount is

$$.577 = 1 - (.25 \times .46) - \frac{.38 \times .46}{1.08} - \frac{.37 \times .46}{1.08^2} .$$

The first component represents the purchase of the system. The second is the tax benefit[10] for the first year's depreciation. The next is the discounted tax benefit for the second year's depreciation. The last is the discounted tax benefit for the third year's depreciation.

B. "Salvage Value of System A (f_{12})"

The next factor of option 1 is the salvage value of system A at the end of the four-year period. Our estimate of the salvage value is 30% of the purchase price, or $221,000. In the model, the value of this factor is -$221,000 since it represents a positive cash flow.

7. Note that f_{pj} and f_{qk} are the same common independent variable in the two cost equations.

8. If we are considering more than two options, we need to treat common factors in a pairwise manner with respect to the least cost option.

9. We assume an 8% corporate cost of money.

10. This example is taken from a real problem that was modeled during 1986. The tax rates and depreciation schedules used are taken from the problem and do not reflect the new tax laws for 1987.

In present value terms, the amount of this factor is

$$.429 = \frac{.54}{1.08^3}.$$

Note it is assumed that System *A* is fully depreciated for tax purposes at the end of the study. Therefore we realize only 54% of the expected salvage value.

C. "Salvage Value of System *B* (f_{13})"

We estimate the sell market value for system *B* as $800,000. The model factor value is therefore -$800,000. In present value terms, the amount of this factor is .54. This assumes that the system has been fully depreciated for tax purposes.

D. "Maintenance Cost of System *A* (f_{14})"

After the warranty period, we estimate the yearly maintenance cost as $8,280. In present value terms, the amount of this factor is

$$2.60 = .023 + \frac{1}{1.08} + \frac{1}{1.08^2} + \frac{1}{1.08^3}.$$

Note that the first component, .023, takes into account the warranty period.

E. "Environmental Cost of System *A* (f_{15})"

The estimated yearly environmental (space, power, cooling) cost of operating system *A* is $15,500. In present value terms the amount of this factor is

$$3.58 = 1 + \frac{1}{1.08} + \frac{1}{1.08^2} + \frac{1}{1.08^3}.$$

7.2 Option 2 Factors and Amounts

A. "Software Costs (f_{21})"

In order to use a production system for testing, we have to run a special software package that costs $60,000 per year. If we exercise option 2, this software will no longer be required. Thus this factor has a value of -$60,000.

In present value terms, the amount of this factor is

$$3.58 = 1 + \frac{1}{1.08} + \frac{1}{1.08^2} + \frac{1}{1.08^3}.$$

B. "Salvage Value of System *B* (f_{22})"

The salvage value of system *B* at the end of the four-year period is estimated as $10,000. The corresponding factor value is -$10,000.

In present value terms, the amount of this factor is

$$.429 = \frac{.54}{1.08^3}.$$

C. "Recovered Production Capacity (f_{23})"

Option 2 includes moving test work from a production system. Since we can reuse this capacity to meet an expected increase in our customer's service demands, we can avoid the installation of an equivalent amount of additional capacity. We estimate our installation cost per millions of instructions per second (MIPS) as $96,300. Thus, the value of this factor is -$96,300. We will move 2.5 MIPS of test work from the production system, so that the amount of this factor is 2.5.

D. "Maintenance Cost of System *B* (f_{24})"

We estimate the yearly maintenance cost of system *B* as $48,200. In present value terms, the amount of this factor is

$$3.58 = 1 + \frac{1}{1.08} + \frac{1}{1.08^2} + \frac{1}{1.08^3}.$$

E. "Environmental Cost of System *B* (f_{25})"

The estimated yearly environmental (space, power, cooling) cost of system *B* is $54,200. In present value terms the amount of this factor is

$$3.58 = 1 + \frac{1}{1.08} + \frac{1}{1.08^2} + \frac{1}{1.08^3}.$$

7.3 Example Linear Programming Formulation

The linear programming that models this decision problem is[11]

minimize

$$.735X_{11} - .221X_{12} - .800X_{13}$$

$$+.00828X_{14} + .0155X_{15} - .060X_{21}$$

$$-.010X_{22} - .0963X_{23} + .0482X_{24} + .054X_{25}$$

subject to

$$X_{11} - .577 \times D_1 = 0$$

$$X_{12} - .429 \times D_1 = 0$$

$$X_{13} - .54 \times D_1 = 0$$

$$X_{14} - 2.6 \times D_1 = 0$$

$$X_{15} - 3.58 \times D_1 = 0$$

11. The factors in the program are written in units of $1,000,000.

$$X_{21} - 3.58 \times D_2 = 0$$

$$X_{22} - .429 \times D_2 = 0$$

$$X_{23} - 2.5 \times D_2 = 0$$

$$X_{24} - 3.58 \times D_2 = 0$$

$$X_{25} - 3.58 \times D_2 = 0$$

$$D_1 + D_2 = 1$$

$$D_1 \geq 0$$

$$D_2 \geq 0 .$$

The solution to this model is

Decision Variable Values	
D_1	0
D_2	1

Stable Factor Ranges		
	Lower	Upper
f_{11}	.617	∞
f_{12}	-.38	∞
f_{13}	-.926	∞
f_{14}	-.0177	∞
f_{15}	-.0035	∞
f_{21}	−∞	-.041
f_{22}	−∞	.149
f_{23}	−∞	-.0693
f_{24}	−∞	.0672
f_{25}	−∞	.073

7.4 Some Observations About the Solution

- Option 2 is the least cost option.
- "f_{11}"

  When the decision is executed, if the purchase price of system *A* is 16% ($118,000) less than our estimate, then our decision is incorrect. This suggests that we should spend some effort to verify our $735,000 estimate.

- "f_{13}"

  When the decision is executed, if the salvage value of system *B* is 16% ($126,000) more than our estimate, then our decision is incorrect. Again, this suggests that we should spend some effort to verify our $800,000 number.

- "f_{21}"

  If we do not save at least $41,000 per year on software costs if option 2 is selected, then our decision is incorrect. We should verify that we will be able to terminate the required software on the production system.

- "f_{23}"

  We need to save at least $69,300 per MIPS by moving test work to system *B* in option 2. If the work cannot move or if our cost to install new MIPS falls below $69,300, then our decision is incorrect. This estimate probably needs additional verification.

- The other estimates in our analysis probably have sufficient accuracy for this decision problem.

8. Conclusion

A simple linear programming model for evaluating the financial aspects of the alternatives in an equipment acquisition decision has been developed. The model can be implemented on an AT&T PC6300 with an interactive linear programming system such as LINDO. The major benefit of using the model is the sensitivity analysis of the basic financial estimates that results from the solution of the linear programming problem. The model is easy to use and helps develop insight into the financial assumptions of the decision problem.

ABSTRACT

The MIPS rate of a processor is no longer a valid measure of system performance, because overall system performance depends on many factors. However, instruction timing measurements are still a powerful method to compare processors with the same instruction set. Instruction timing results can also provide interesting insight in the processor's internal operation. In this study the MIPSMON software monitor has been used to time most problem mode instructions on three processors using the IBM System/370 architecture. The results reveal some peculiarities of the processors involved. Instruction mixes, collected with the PPTRAC trace monitor, are used to estimate the MIPS rate in real programs: the instruction frequency and instruction timing data are combined to provide a weighted average. Finally, the potential of a cache analysis program based on the PPTRAC traces is explored.

1. Introduction

The performance of a computer system depends on many factors, among which the speed of the central processor, the size and access time of main and cache memory, the I/O configuration and the operating system. Early systems were characterized with the processor speed only, the power being expressed in terms of millions of instructions executed per second. This measure is called the MIPS-rate. In the current mainframe systems, however, the I/O subsystem and the operating system level have a profound effect on the system performance. Also, the MIPS-rate depends on the workload being executed on the processor.

For these reasons, manufacturers no longer specify a MIPS rate for their machines. Instead, the processor power is expressed as "so many times Model XX". IBM uses the "Relative Processor Power" (RPP), which indicates how fast a processor is, compared to the 370 Model 158-1. Incidentally, everybody knows that the 370 Model 158-1 is a 1 MIPS machine.

Measuring the instruction execution time for individual instructions does not provide a reliable measure for system performance, but it is a powerful method to evaluate the performance of the central processor component (CPU). Since the CPU speed is directly influenced by the cache and main memory speed and organization, the effects of these components will show up in the results as well.

The speed of a processor depends on many factors. [Hughes 1983] and [Bonnes 1983] provide an overview of these. The most important ones in this context are:

- The execution time for each instruction, as a function of the operand length(s).
- The instruction mix of the programs running on the central processor.
- The cache organization, access time and hit ratio, and the main memory organization and access time.

In this paper a method will be described for measuring the execution time of individual instructions using the MIPSMON software monitor, which has been developed at the Delft University [Bonnes 1983]. The measurement method eliminates most disturbances from cache and main memory. It will be shown that many characteristics of the processor hardware can be derived from the timing results.

In addition to the timing data on individual instructions, we have determined the instruction frequency for several applications, with a program called Problem Program Tracer (PPTRAC) [Paans 1986]. PPTRAC collects address and instruction reference streams, which are used to acquire statistics on instruction usage. The combination of the MIPSMON timing results and the instruction stream provides the relative CPU load of each instruction for a particular program mix running on a particular CPU.

The MIPS rate of a program depends not only on the instruction mix, but also on the address and instruction reference pattern. The pipelining in the processor, the cache implementation, the pattern of storage references and the translation look aside buffer all influence the processor MIPS rate. We will present a method for obtaining statistics on cache usage by a program based on the instruction reference streams. Many problems remain, however, and it is not possible to quantify the cache performance completely from the measurement data.

2. Description of the processors

All measurements have been performed on three implementations of the IBM System/370 architecture: the IBM 3033N, the IBM 3083B and the Siemens 7890D. The hardware implementation of these processors is quite different. Table 1 summarizes some of the characteristics of the processor hardware. These numbers are obtained from the documentation supplied by the manufacturers [IBM 1982a][IBM 1982b][IBM 1983][Siemens 1982], supplemented with estimates from our measurements[2].

1. Although the author is currently employed by IBM, the opinions expressed together with the recommendations made are strictly his own and have not been subjected to any formal IBM review.

2. main memory contains global buffer, access time depends on hit ratio

TABLE 1. Summary of the processor characteristics.

characteristic	processor			
	IBM 3033N	IBM 3083B	Siemens 7890D	
Machine cycle time	25/32	26	appr. 30	ns
cache access time	appr. 60	52	appr. 60	ns
cache size	16	32	16	Kbyte
cache block size	64	128	64	byte
main memory access time	342	312		ns
main memory size	16	16	16	Mbyte

The machine cycle time and the cache access time can be easily derived from the MIPSMON results, as will be shows below. In fact, the Siemens timing data were obtained from the measurements. The IBM 3033N and the Siemens 7890D use a store-through cache memory, while the IBM 3083B uses a flagged-swap cache memory. In a store-through cache memory, each write operation from the processor is immediately propagated to the main memory, blocking the cache memory for some time. In a flagged-swap cache, writes are propagated to the main memory only when the cache block contents are removed because the block is required for more recent data. The advantage of a flagged-swap cache is that it reduces the traffic between CPU cache and main memory significantly. A disadvantage is the more complex logic needed to implement the cache.

The Siemens 7890D uses a "global buffer" on the main memory, to reduce the main memory access time. In fact, it is an additional cache memory, be it somewhat slower and larger. In a multiprocessor 7890 system, each CPU would have its own cache ("local buffer"), but still use the same global buffer.

3. Measuring the Instruction Execution Time

The Instruction Execution Time (IET) is the time required to execute a single instruction. It is not possible to measure this time directly, except possibly with a hardware monitor. Even then it will be difficult to follow an instruction through the phases of instruction fetch, decode and execution as it flows through the processor pipeline.

The MIPSMON software monitor uses a different approach: the instruction to be measured is executed many times, and the total time required is measured using the CPU timer. The MIPSMON monitor consists of a driver program, which collects the timing information, and a separate module for each instruction to be measured. Each instruction mix module consists of 100 instructions of the type to be measured (and a subroutine return instruction). The driver calls the module N times, and measures the total time. Since the total time, and the number of times the instructions are executed are known, the IET can be computed. The measurement method is depicted in more detail in Figure 1.

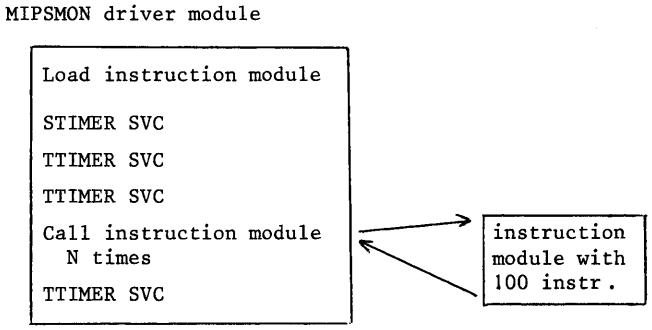

Figure 1. Overview of MIPSMON operation.

The MIPSMON driver consists of the command interpretation modules and the reporting modules, the code to load and execute the instruction mix and the timer facilities. The instruction mix module is loaded separately for each measurement.

The CPU time used is found by means of the timer services provided by the operating system. The MIPSMON driver first initializes the timer (STIMER), then it determines the timer overhead (first two TTIMER calls), and finally times the instruction mix (last TTIMER call). The MIPSMON driver will determine the average instruction execution time from the timer values and the number of calls to the module. It is assumed that the module contains 100 instructions.

The IETs found only depend on the processor speed and the cache access time, since only a tight loop is executed: all data referenced will be available in the cache memory after a single run through the loop. For most instructions, the main memory access time will have no influence on the IET obtained with MIPSMON. This is of course not a typical situation for a real program; therefor the results will thus be optimistic in that sense, but for this application it is more important that they are well defined and reproducible. MIPSMON jobs have been run at widely varying load, and the results always matched within 1%.

4. Instruction Timing Results

The IET has been determined for most of the problem mode instructions. In general, the instruction execution time depends on a large number of different factors, divided into the "history" of the instruction on the one side, and the instruction and its operands on the other side. In the interpretation of the MIPSMON results, we will only consider the instruction type and the operand length as variables. All other effects are neglected.

4.1 RR- and RX instructions

The fastest instructions on a System/370 processor are the Register-Register (RR) operations, which use registers only. Register-Indexed (RX) operations use a register and storage operand, which may require some additional effort from the processor. Both RR and RX operations may deal with integers (32 bit signed) and reals (64 bit floating point). Some other types are defined as well, but these will not be discussed here. Table 2 shows the timing results for load (L), add (A) and divide (D) instructions for the data and instruction types mentioned.

TABLE 2. Execution time for some RR and RX instructions (all results in nanoseconds).

instruction type		processor 3033N	3083B	7890D	
LR	RR, integer	60	54	60	ns
AR	RR, integer	60	54	60	ns
DR	RR, integer	1170	945	773	ns
L	RX, integer	88	80	60	ns
A	RX, integer	88	105	60	ns
D	RX, integer	1116	970	730	ns
LDR	RR, real	60	80	60	ns
ADR	RR, real	217	220	88	ns
DDR	RR, real	1750	1130	705	ns
LD	RX, real	88	132	60	ns
AD	RX, real	221	202	90	ns
DD	RX, real	1750	1156	710	ns

These results should be compared with the the CPU cycle time and cache access time from Table 1. The RR-type integer load and add instructions, with a 16 bit opcode, execute in two cycles. For the 3033 25+32 ns, for the 3083 2*26 ns and for the 7890 2*30 ns. This is also approximately the cache access time. The corresponding RX instructions, with a 32 bit opcode and a storage operand, require additional effort to read the operand. For the 3033 the execution time is now 88 ns (3 cycles) for both the load and add operations. The 3083 requires 80 ns (3 cycles) for the load, and 105 ns (4 cycles) for the store. The reason can only be that the 3083 requires an extra cycle to store the result from the add operation, after the memory operand has been fetched. The 7890 CPU is quite clever, it processes both RX-type operations at the same speed as their RR-type equivalents. Although not presented here, the results for the logical, subtract and compare operations are analogous for all CPUs.

Instructions for multiplication and division require considerably more CPU time. The limitation here will be the power of the arithmetic unit of the processor: a division requires a lot of cycles or a large number of circuits. For the integer division, the 3033 is the slowest machine (approximately 40 cycles), and the 7890 the fastest (approximately 26 cycles).

The floating point operations again show the power of the 7890 processor: the RR and RX load execute in two cycles, the adds in three. The 132 ns access time for the 3083 LD instruction is remarkable: why does the processor need 5 cycles for a simple load operation? It seems there is bottleneck in one of the internal busses of the processor, which slows down a fetch from memory.

The cache design is reflected most directly by the store operations. For a store-through cache, each store requires a main memory update, while a flagged-swap cache stores in the cache only. The data is propagated to main memory only when the cache block is needed for other data. Table 3 shows the timing results for the load and store operations.

TABLE 3. IET for load and store operations in nanoseconds.

instruction	processor 3033N	3083B	7890D	
Load (RX, integer)	88	80	60	ns
Store (RX, integer)	283	105	175	ns

The 3083 easily outperforms the other CPUs for store operations due its flagged swap cache. The 7890 is faster than the 3033, probably due to its global buffer. It is interesting to note that even for the 3033 the average IET of a store instruction is less than the specified main memory access time shown in Table 1 (283 vs 342 ns).

4.2 Jump Instructions

Jump and conditional jump instructions are important for the MIPS rate, since they occur frequently in all programs. Table 4 shows the IET timing results for some jump instructions.

TABLE 4. IET for various jump instructions in nanoseconds.

instruction	processor 3033N	3083B	7890D	
BALR (RR jump & save)	200	130	80	ns
BCTR (RR, jump not taken)	170	100	90	ns
BCTR (RR, jump taken)	170	130	130	ns
BCR 0 (no operation)	60	80	60	ns
BCR 15 (unconditional jump)	200	130	80	ns

The Branch And Link Register (BALR) instruction saves the next instruction address in the first register, and jumps to the address specified in the second register. The Branch on CounT Register (BCTR) instruction decrements and tests a register value, and branches if the registers contents are not equal zero. The Branch (Conditional) Register (BCR) instruction is a conditional jump instruction. The operand specifies the processor status bits to be used in the test (0 and 15 are special cases).

The 7890 is again the faster machine: unconditional or failing jumps take 3 cycles, and the conditional BCTR instruction takes 4 cycles if a jump a required. The 3083 is similar, in that a conditional branch instruction is faster if no branching is needed. It is remarkable that the BCTR executes as fast as the BCR 15 on the IBM machines, despite the register update required. The Siemens machine requires two additional cycles for the register update. The IBM machines will probably prepare the jump in parallel with the decrement and compare, while the Siemens serializes these events.

It is interesting to note that the 7890 processor documentation [Siemens 1982] states that 5 cycles are required for a successful jump, while the measurements suggest a value of 3. The BCTR instruction indeed takes four or five cycles. The difference might be caused by the MIPSMON measurement method, where all jumps skip only a few instructions and the destination instruction has already been processed in the pipeline.

4.3 Decimal Instructions

Instructions to process packed decimal numbers are relatively slow, because the format is not easily handled in a binary computer; to achieve a reasonable performance, a significant amount of dedicated hardware is required. The IETs for the decimal instructions differ significantly for the CPUs studied, as is shown in Table 5.

4.4 Block Move and Compare Instructions

The MVCL and CLCL instructions move and compare a block of data respectively. These instructions use 4 registers, to specify source and destination addresses and lengths. Table 6 presents the timing results for some block sizes, from 1 byte to 8 Kbyte.

TABLE 5. IET for some arithmetic instructions in nanoseconds.

		processor			
	instruction	3033N	3083B	7890D	
A	4 byte integer	88	105	60	ns
AD	8 byte real	221	202	90	ns
AP	4 byte decimal	890	459	381	ns
(add)	8 byte decimal	1111	560	380	ns
	16 byte decimal	1719	763	425	ns
ZAP	4 byte decimal	779	434	497	ns
(move)	8 byte decimal	1001	535	497	ns
	16 byte decimal	1499	763	599	ns
M	4 byte integer	281	382	162	ns
MD	8 byte real	520	405	132	ns
MP	4 byte decimal	2988	1738	1480	ns
(mult.)	8 byte decimal	5209	1471	1480	ns
	16 byte decimal	19031	8563	3565	ns
D	4 byte integer	1116	970	730	ns
DD	8 byte real	1750	1150	710	ns
DP	4 byte decimal	4793	7265	1467	ns
(divide)	8 byte decimal	16285	10908	2837	ns
	16 byte decimal	31415	33463	4312	ns

In this table it is remarkable that the 7890 processes 4 and 8 byte operands at the same speed (except for the divide, which requires a double width temporary value). The 7890 ALU must be able to process 8 byte quantities, where the 3033 and the 3083 are limited to 4 byte values. These results agree with those found for the RR and RX instructions, where the 7890 processed real numbers (8 byte) at the same speed as integers (4 byte), while the 3033 and 3083 required additional cycles.

The MP and DP instructions are the only instructions whose execution time is not linear in the operand length. This is a direct consequence of the multiplication and division algorithms used, which are quadratic in the number of digits processed, unless extensive hardware support is available.

The 7890 is equally fast for compare and move operations. An 8196 byte operation takes about 4000 cycles, or 2 cycles for each fetch or store operation on a 8 byte unit. Since the cache access width is about 8 byte, this will be the maximum rate supported by the cache.

In this time, not only the copy/compare operation has to be performed, but also the register update for the base address and counters. The CLCL and MVCL are interruptable and restart from the previous results, not from the beginning of the operation, so the registers must be kept up to date.

The 3083 requires roughly 6000 cycles for an 8196 byte copy, or 3 cycles for each fetch or store operation on a 8 byte unit. Probably this is due to limitations in the CPU hardware for the register update.

TABLE 6. IET for the compare long (CLCL) and move long (MVCL) instruction, as a function of the operand length. All timing results are in nanoseconds.

		processor			
	instruction	3033N	3083B	7890D	
CLCL	1 byte	2181	695	530	ns
	4 byte	2181	696	530	ns
	16 byte	2298	935	781	ns
	64 byte	3346	1834	1516	ns
	256 byte	7540	5322	4459	ns
	1024 byte	26009	20718	16247	ns
	8196 byte	216112	165065	129170	ns
MVCL	1 byte	2689	1919	1195	ns
	4 byte	2838	1919	1195	ns
	16 byte	2883	2105	1348	ns
	64 byte	3598	2905	2023	ns
	256 byte	6439	6095	4401	ns
	1024 byte	20145	22067	13945	ns
	8196 byte	131157	177347	131800	ns

TABLE 7. Instruction frequency top-10 reported by PPTRAC for 5 application programs (see text for details).

progr.	COBOL001		SMFPOST		APPLIC01		APPLIC02		SMFCOUNT	
#instr	1,000,000		2,000,000		183,078		2,779,581		284,901	
instr	opcode	%	opcode	%	opcode	%	opcode	%	opcode	%
1	BC	21.3	BC	21.4	BC	23.4	BC	18.6	BC	19.7
2	ZAP	20.3	L	8.8	L	10.3	L	11.0	L	10.0
3	CP	15.1	LA	6.6	TM	9.1	ST	6.1	TM	8.0
4	MVC	5.8	ST	6.4	LA	7.0	LA	6.1	LA	7.4
5	L	5.8	BCR	4.7	ST	4.7	MVC	6.0	MVC	6.0
6	SP	4.2	CLI	4.5	LR	3.9	CP	4.8	SR	4.8
7	DP	3.1	MVC	4.4	CLC	3.4	LR	4.3	IC	4.8
8	MP	2.9	MVI	3.3	MVC	2.9	SR	3.8	ST	3.8
9	XC	2.6	TM	3.2	MVI	2.7	AR	3.6	LR	3.5
10	LA	2.5	IC	3.1	SR	2.7	BCR	2.9	AH	2.5
# svc's	40	0.0	979	0.04	1523	0.8	185	0.0	287	0.1

The 3033 is "slow" for the compare operation, about 8000 cycles for an 8000 byte compare. Since the move operation is fast, the difference will probably be caused by limitations of the ALU in performing the compare operation. Another possibility would be that the processor is optimized for the move operation.

5. Collecting Instruction Traces

In the previous sections it was already mentioned that it is necessary to know which instructions occur how often (on the average) to determine the MIPS rate on a system. Unfortunately, it is impossible to collect this kind of statistics in a real system, on a real time basis. We have chosen an approach where a few programs, which are believed to be representative for the production workload on the system, are traced instruction by instruction. The traced instructions and their operands are then saved in a file for future analysis.

In System/370 computers it is not possible to trace a program on instruction basis with standard facilities: no hard- or software single step support is available to the user. At the Delft University, the software monitor PPTRAC (Problem Program Tracer) has been developed to cope with this problem [Paans 1986]. PPTRAC traces a program by executing it instruction by instruction: it determines which instruction has to be executed, loads the registers, executes the instruction and saves the registers. The instruction executed, its address and operands are saved in an output file. PPTRAC traps a few SVCs, changing the operands before the SVC is invoked. The SVC code itself is not traced.

During the trace process, an output dataset is created with the instruction addresses, opcodes and parameters. This data can be used to produce statistics on instruction frequency, to drive a cache simulator (based on the addresses), or it can be combined with the timing results from MIPSMON to provide a weighted MIPS-rate for the traced program.

The PPTRAC program has been used to trace 5 application programs. For each program, the top-10 instructions by frequency are shown in Table 7.

The APPLIC01 and APPLIC02 programs are database applications, written in COBOL. SMFPOST and SMFCOUNT are assembler programs to analyze SMF records, and COBOL001 is a COBOL program for SMF reporting.

It is remarkable that the conditional branch instruction (BC) is the most frequent instruction in all programs, at about 20%. Other frequent instructions are load (L, about 10%), store (ST), load address (LA), move character (MVC) and test (TM) each at roughly 5%. The COBOL001 program is a case in itself: this program uses packed decimal instructions extensively to handle decimal numbers. This program will be discussed in detail in a next section.

6. Computing the Real MIPS Rate

While the instruction frequency is interesting measure, it gives no indication of the processor usage of each instruction. A frequently used instruction may execute very fast, while another infrequently occurring, may be very slow, making its total CPU demand larger. Also, the execution time of an individual instruction depends very much on its operands: a compare over 8 bytes executes much faster than one over 8000 bytes.

TABLE 8. Processor utilization per instruction for the SMFPOST assembler program on the three CPUs.

no	IBM 3033N CPU			IBM 3083B CPU			Siemens 7890D CPU		
	opc	freq %	CPU %	opc	freq %	CPU %	opc	freq %	CPU %
1	BC	21.41	14.56	BC	21.41	16.71	BC	21.41	12.91
2	MVC	4.38	11.28	MVC	4.38	11.65	MVC	4.38	12.49
3	ST	6.42	8.23	ZAP	1.70	5.43	ST	6.42	9.29
4	ZAP	1.70	6.36	LM	1.60	5.10	ZAP	1.70	7.14
5	CLI	4.58	5.79	L	8.83	4.92	CLI	4.58	5.57
6	CLC	2.45	5.37	CLC	2.45	4.77	LM	1.60	4.93
7	STM	1.12	5.31	ST	6.42	4.69	L	8.83	4.38
8	MVI	3.26	4.13	STM	1.12	4.54	TR	0.01	3.70
9	AP	0.97	3.90	CLI	4.58	4.21	STM	1.12	3.63
10	BCR	4.65	3.89	BCR	4.65	4.03	LA	6.60	3.28
	MIPS		4.529	MIPS		6.956	MIPS		8.271

To cope with this problem, the relative CPU utilization should be reported instead of the instruction frequency. This number can be obtained from the instruction trace collected by PPTRAC, which contains all instructions and their operands, combined with the timing data collected by MIPSMON, being the execution time for all instructions as a function of the operand length. A separate report is now needed for each processor. Table 8 shows the top-10 based on CPU utilization for the SMFPOST assembler program from Table 7.

The ranking in these tables is quite different from Table 7. The branch instruction is still important, but the utilization is only 12-16% percent, as opposed to a 21% occurrence frequency. The store (ST) instruction ends up higher for the 3033 and 7890, and lower for the 3083 due to its flagged-swap cache operation. Expensive instructions like the ZAP, LM and STM, which are each quite infrequent (less than 2%), end up with utilizations between 3 and 7 percent. The translate (TR) is a case in point: an occurence frequency of 0.01%, and a CPU load of 3.7% on the 7890 CPU.

The bottom line in the table shows the MIPS rate as computed for these programs. These MIPS rates are more or less the "typical" values to be obtained for an application program on these processors.

In this paper only results for user-programs were reported. The full set of MIPSMON measurement results include some privileged instructions; also, PPTRAC has been used to trace some operating system functions in an MVS SE2 system. However, insufficient data was collected to predict the performance of operating system code in general. Data obtained so far indicates that instruction mixes of supervisor routines also consist mainly of the type of instructions found in user programs. Priviliged instructions are hardly used.

There are also fundamental problems involved in measuring privileged instructions: it does not always make sense to perform MIPSMON IET measurements on privileged instructions. Does it help you to know how much time it takes to execute a mix of 100 PURGE TLB instructions? (By the way, it takes 550 microseconds on a 3081-D [Paans 1986]).

7. A Case Study: Decimal and Binary Arithmetic

The COBOL001 program in Table 7 showes a very large fraction of decimal instructions, which are slow on System/370 machines. Table 9 shows the MIPS rate for this program, and the relative load for each instruction. The results are striking: the MIPS rate is down to 1.4 for the 3033 and 3 for the 7890.

The decimal instructions are very expensive to execute, which is reflected in the results in this table. The branch instruction (which is the most frequent one), is down to the 6th, 5th and 7th place for the 3033, 3083 and 7890 respectively. The COBOL compiler generates large numbers of decimal instructions like ZAP, AP, CP, MP and DP if the packed format is specified for variables. To investigate the influence of the format specification on the code produced, some of the more frequently used variables were changed to a binary format. A new trace shows a quite different

TABLE 9. Relative processor utilization and instruction frequency for the COBOL001 program.

	MIPS		2.328	MIPS		3.305	MIPS		4.203

program: from the PPTRAC instruction trace it appeared that the total number of instructions is reduced by a factor 2.2; and the MIPS rate increases by more than 50%. The total performance improvement is more than 400%. The top-10 results are given in Table 10. The decimal instructions are still important, and conversion instructions now show up (convert to binary (CVB) and convert to decimal (CVD)).

It is sometimes suggested that conversion between data types should not be used, since expensive conversion instructions are required to convert the different types into each other [IBM 1976]. From the MIPSMON results it appears, however, that even the simplest decimal instruction like AP takes as much time as a convert instruction. The conversion overhead will thus usually be low compared to the savings obtained by the use of binary arithmetic.

8. Scope of this work

In the analysis as described above, only the average execution time of instructions and their frequency of occurrence were considered. We did not take into account the instruction sequencing, we did not model the cache and translation look aside buffer, we did not incorporate task switching nor operating system behavior.

The MIPS rate achieved in a real system depends strongly on the pipelining effectiveness and on the percentage of translation look aside buffer and cache hits. These quantities, in turn, depend on the storage reference pattern of the programs running, and on context switching.

The effectiveness of the prefetching and pipelining hardware in the CPU critically depends on the instruction sequence; an unexpected "far" branch makes the preloaded information useless. Using instruction traces collected with PPTRAC, it would be possible to predict how often such branches occur. In a more general sense, one could adjust the execution time of an instruction, based on the previous one(s). The problem with these "high order" approximations will be in measuring of suitable timing adjustment values.

The performance of the cache memory depends on the locality of reference; the cache will buffer the information most recently accessed. When a new area of storage is being referenced, as occurs when a new task gains control of the processor, a copy of this storage will not be available in the cache. The task experiences a cache miss for each new address (or group of addresses) not previously referenced. Each cache miss requires a reference to main storage, which is usually much slower than a cache reference. During the execution of the task, the cache will be filled for this task, replacing data from previous tasks. The longer a task runs, the more data of previous tasks will be unavailable in the cache.

For the best overall cache performance, the average path length (the number of instructions executed without interruption) should be long. When a task gains control of the processor it may find storage areas from a previous execution still in the cache. This is of course dependent on the size of the cache and on how long ago this task was last active. In an MVS environment, the latter information could be obtained from a GTF trace [Bonnes 1984][IBM 1985]. A study on task locality is reported by [Kobayashi 1986].

With an appropriate approach it seems possible to combine the MIPSMON, PPTRAC and task-switch information into a single model of CPU behavior. Using the same approach, workload components like a swap-in could be described in terms of task-switches and instruction reference patterns.

9. Conclusions

The analysis method as presented provides a powerful method to compare the speed of processors in the IBM System/370 range. The approach is based on instruction timing measurements, in combination with instruction traces. The method can also be used to evaluate the quality and efficiency of code generated by compilers. An example has been discussed where the use of binary instead of decimal arithmetic yielded a performance improvement of a factor 4.

For analyzing the system performance the method must be extended to incorporate the cache and translation look aside buffer effectiveness, and the performance impact of task-switching. The major problem with this approach is that it seems almost impossible to collect trace data for operating system components in anything but a test situation.

Tightly-Coupled Effect Processor Contention Overhead

Jerry P. Place

Kansas City, MO 64110
(816) 276-2359

Abstract. Tightly coupled parallel systems are increasingly prevalent. IBM's 3090-600E will have six tightly-coupled processors running under MVS. While these configurations of tightly-coupled processors have advantages such as straight-forward resource sharing and medium-granularity parallelism, there are some drawbacks. The drawbacks are called the *tightly-coupled effect*. The tightly-coupled effect states that a workload executed on a multiprocessor configuration can consume more processor overhead than the same workload executed on a uniprocessor. This paper will present one major aspect of the tightly coupled effect - processor contention for the dispatching queue - and will indicate the degree of the effect across different levels of total system utilization.

Key Words. data structure contention, shared-memory multiprocessing, tightly coupled multiprocessing, dispatching, process scheduling.

1. Introduction.

Tightly-coupled configurations of computing machines are widely available today from several vendors. It has been recognized that tightly-coupled configurations of computing machines offer substantial benefits such as data sharing, device sharing and medium granularity parallelism. Parallel configurations are also seen as a possible alternative to bigger and more powerful single processor systems, i.e. instead of installing a bigger, more powerful uniprocessor, install a tightly-coupled configuration and allow these machines to work together to solve problems.

Control in tightly-coupled systems fits into one of three categories *master/slave, separate supervisor,* and *floating control*[1]. The *master/slave* mode assigns one of the processors in the configuration as the master. The operating system kernel routines always execute on the master. The master is responsible for dispatching work to the slave processors. The *separate supervisor* method of control maintains a copy of the operating system kernel for each processor in the system. Other system entities such as tables and common routines must be accessible through shared memory or a shared file system. The *floating control* method maintains one copy of the operating system and each processor executes that one copy. Thus, each processor is responsible for satisfying its own requests for service. Floating control systems are the most difficult to design and implement. The single copy of the operating system must be reentrant and, since key system data structures must be shared by all processors in the configuration, constructs to ensure determinism must be embedded in the operating system.

In order to ensure determinism in a system, only one processor at a time will be allowed to access a common data structure when several processors require read/write access to the structure. While there are many resources within a tightly-coupled operating system that fall into this category, this paper will focus on the system dispatching queue. If $processor_a$ cannot gain access to this structure because $processor_b$ has exclusive access, $processor_a$ must wait - *spinning on the lock.* that guards the queue. Figure 1 depicts a configuration of processors about a shared memory. Each process in the system is divided into its component tasks. All tasks competing for resources in the configuration are represented by task control blocks in the dispatching queue. The task control blocks indicate the status of the task - either dispatchable or not, and the dispatching priority of the task. Since processors share all system resources, the processors are considered equivalent, thus any task may execute on any processor - regardless of the tasks that are executing on other processors. It is possible that several tasks from the same process will be executing in parallel on different processors in the system. As a task executes, events occur that cause it to be blocked - perhaps an I/O request, or a page fault. When an executing task is blocked, its processor is context switched, i.e. another task is *dispatched* to that processor.

The dispatching mechanism is enacted by each processor executing the shared copy of the dispatching process. In essence, floating control in this specific example means that each processor must find its own job to execute next - independently of all the other processors. A processor finds its next unit of work by searching the *system dispatching queue* - generally implemented as a linked list of task control blocks. Since each processor will update one or more task control blocks on the dispatching queue, i.e. mark the task control block as *blocked* when the task is blocked for I/O or a page fault, the dispatching queue must be a serially reusable resource in order to ensure determinism in the system[2]. Thus, in order to access the dispatching queue, a processor must exclusively own the *dispatching lock* which guards the queue, i.e. only one processor at a time may use the dispatching queue.

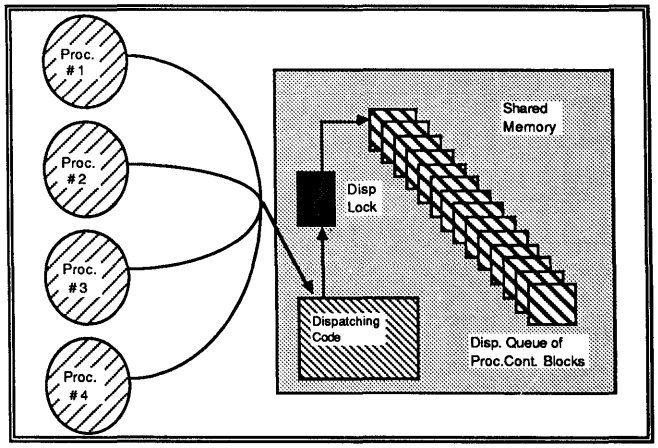

Figure 1 - Tightly-Coupled Configuration

2. System Data Structure Contention.

The shared *READY* queue is a point of contention among processors in the configuration[3]. This contention is part of measured CPU utilization in a tightly-coupled system and constitutes significant overhead per processor which is sometimes referred to as the *tightly-coupled efect*[4,5]. Figure 2 presents a simple queueing model that reflects the contention for the dispatching queue. The assumptions of the model are:

- Ts_1 is the dispatching queue service time, $Ts_1 = 13\mu s$.
- Ts_2 is the average time that each process will execute before a context switch,

  $Ts_2 = 500\mu s$.

• Ts_3 is the time each processor can expect to spend idle, Ts_3 is determined from the input.

• All processors are homogeneous.

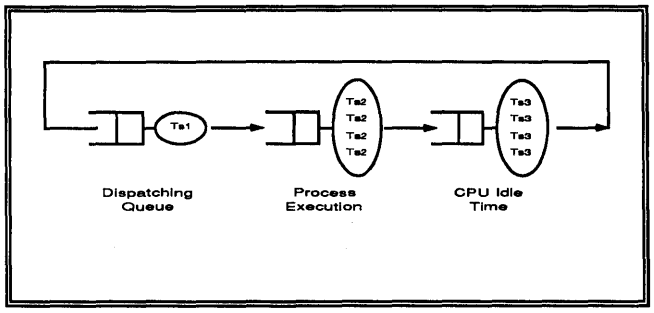

Figure 2 - Processor Scheduling Queueing Model

Only one processor at a time may access the dispatching queue. It takes each processor Ts_1 seconds to find a task to execute. When a processor finds its next job, it executes an average of Ts_2 seconds then the processor is idle for Ts_3 seconds. Assumptions for this simple model are based upon an average of 200 task control blocks on the dispatching queue and a memory cycle time of 100ns.

Figure 3 presents the results of executing the model at average processor utilization levels of 20%, 40%, 60% and 80%. The model then was executed for tightly-coupled configurations of one through sixteen processors - at each average utilization level. The chart provides a measure of the impact of increasing contention for the dispatching queue as the number of processors in the configuration increases. The percentage amounts in the chart were computed as $\frac{W_1}{W_1 + W_2}$ where W_1, W_2, and W_3 are computed wait times at each node in the model. The percentage amounts in the chart may be interpreted as the percentage of execution time (CPU utilization overhead) that could be attributed to the dispatching function. It is emphasized that the percentage is on a per-processor basis, thus 3.56% contention overhead on each processor in a configuration of sixteen processors means that about 3.56% * 16 = 0.5696 or just over 1/2 of a processor is consumed by dispatching queue contention across the parallel configuration.

Average dispatching contention overhead ranged from a low of 1.3% of CPU execution time per processor to 3.56% per processor (see figure 3). As expected, the lowest queue contention overhead occurred at low average processor utilization and the highest contention overhead was recorded with a configuration of sixteen processors each with an average utilization of 80%.

3. Conclusion

This study is important for several reasons. Contention overhead is an important factor that must be considered when deciding whether to run a system loosely-coupled or tightly-coupled. Also, contention overhead could be an important consideration when reviewing a possible tightly-coupled configuration that will replace an existing uniprocessor.

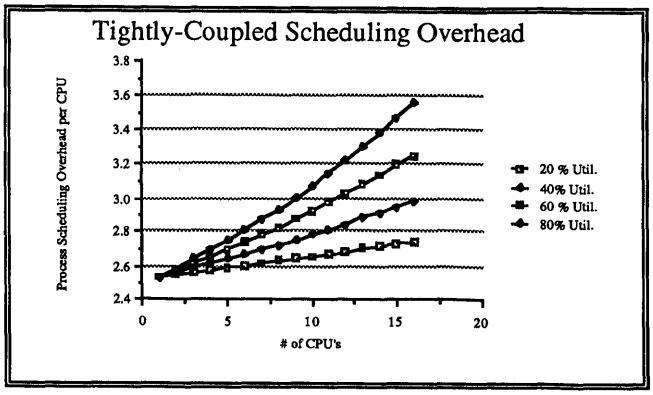

Figure 3 - Processor Scheduling Overhead

The actual overhead percentages obtained by this study are not particularly important. The average task execution time between context switches is dependent on the nature of the system workload. The most important point made by this study is the relationship between dispatching queue contention overhead and the number of processors in a tightly-coupled configuration and the impact that average processor utilization can have on the contention overhead.

FORECASTING CPU UTILIZATION IN AN IMS ENVIRONMENT: A CASE STUDY USING MONTE CARLO TECHNIQUES

W.T. Gray, M. Cheng
Canadian Pacific

ABSTRACT

Canadian Pacific runs three large 3090 class processors dedicated to IMS. Over one hundred separate production applications execute well over 2 million transactions per day. To forecast future resource requirements, the capacity planning group has evolved a sophisticated forecasting technique.

In a quarterly process, the project managers for each IMS application provide a forecast of the average number of transactions which they expect to see executed each day. Aided by historical actuals and their previous estimates, they return a forecast with it's upper and lower bounds. This forecast and sampled system data is input to a Monte-Carlo simulation. The output from the simulation is a distribution of projected CPU utilizations. From this we can make a statement like: we expect a machine to be 70% busy by the end of the fourth quarter but there is a 20% probability it will be 85% busy.

In comparing actual results with forecasts from previous periods, we see that the process has correctly bound the results. The procedure also has the virtue of wide management acceptance.

OVERVIEW

In the first section of this paper, we describe how transaction forecasts are gathered. The second section discusses the calculation of CPU utilization from these forecasts. The next section describes random variables and the application of the Monte Carlo technique to this problem. In the next section, we discuss extentions of the technique to a more complex environment. Following this, we describe how to perform sensitivity and "what if?" analysis. Finally, we discuss the general applicability of the technique, its strengths and weaknesses.

FORECASTING

There are many different ways to forecast demand. In our case it is possible to get a good forecast from the user community out six quarters. This is a fortunate not only from the point of view of accuracy, but also of accountability.

Whenever you go to a user for a forecast, there is a problem. You want CPU seconds and they have invoices processed. You can use their metric and translate it to yours by some multivariate technique. You can train the user to think about CPU time. This can work if the user is billed in units of CPU time. We make a compromise and forecast in terms of transactions. The user community understand transactions. They are a simple concept and the user can relate them to work units within their individual environment. They are an ideal compromise for us in that we can track transactions and the CPU time they consume. They also have the advantage that they do not change when the processor or the operating system changes. Non-technical managers accept them for their simplicity and because they can add them together over multiple CPUs and multiple datacenters. This is useful in depicting overall load changes, especially when we move applications between processors or sites.

From a capacity planning point of view, transactions are quite a different matter. For one thing, they're all different. Each consumes different resources, at different times of the day, on different machines, in different regions. The problem for the capacity planner is translating a transaction forecast into a forecast of resource utilization.

There are two ways to group transactions: by some manner of resource usage, or by application. From a performance point of view, the best way to deal with transactions is by some resource consumption category (eg. small, medium, large). For performance purposes, it is immaterial which user submitted the transaction. For Capacity Planning, the size of the transactions is immaterial. The size of the application is the critical element. We do not classify transactions within application. We could request that the user forecast the number of small and large transactions within their application, but we feel that this is unnecessary. We only require that the mix remain somewhat constant, and this is usually the case.

There are many sources of variability in the transaction volume for an individual application. Not only does the transaction volume vary from day to day, but the project manager's forecast is only a guess. To understand the variability, we ask that they supply a minimum guess, a maximum guess, and a "most likely" guess. To help guide the project managers in this task, we provide the last six quarters of actuals and their last forecast. The format of all this data is minimum-mean-maximum. At each iteration of the process we ask that they look at the previous forecast and change it if they see fit. At the same time we ask them to forecast out another quarter such that the forecast always extends six quarters.

Figure 1 is an example of the type of form which we send to the project managers. The last three columns represent the last forecast

supplied to us. The project manager has not seen the 87Q2 actuals before. We have added the 87Q4 blank line. The project manager is to examine the forecast in light of the actuals, modify it if he or she sees fit and estimate one more quarter.

Figure 2. Returned forecast form.

The corporate office automation system is the medium for mailing and returning these forms. We maintain the forecast information on a database, accessible to both the electronic mail system and our SAS based programs. The forecast collection portion of the system runs almost completely under program control such that there is no lengthy key entry step.

PROCESSOR MEASUREMENTS

When a machine is running on average, 80% busy across prime shift and if prime shift were 10 hours long, then BUSY time is 8 hours and IDLE time is 2 hours. When we refer to forecasting percent utilization we are talking about forecasting the number of hours of BUSY time. Figure 3 below shows schematically the allocation of all CPU time. This figure represents a pure IMS environment. In other words, there is no TSO or batch.

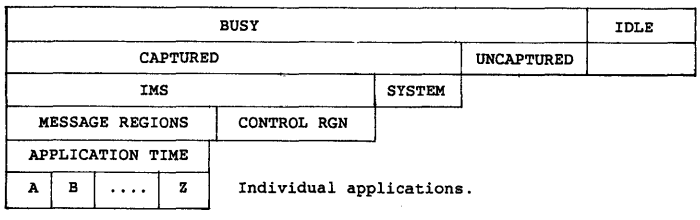

Figure 3. Schematic of time recording on "pure IMS" machine.

Within BUSY time, there is time which the operating system cannot allocate to any specific task; rather, it is work done for the entire system. Consistent with convention, we refer to this as UNCAPTURED time and the ratio of CAPTURED time to BUSY time as the SYSTEM CAPTURE RATIO.

$$\text{SYSTEM CAPTURE RATIO} = \text{CAPTURED}/\text{BUSY} \quad (1)$$

Since RMF records BUSY time, we can always calculate UNCAPTURED time by subtracting CAPTURED time from BUSY time. The best way to calculate the total CAPTURED time is to sum all the CPU time from each performance group.

We can divide CAPTURED time among the tasks which use it. In our example, we decompose this time into IMS and SYSTEM. We define SYSTEM as the operating system and started tasks (MVS/JES, VTAM, ACF, etc.). Within the IMS portion, we include the message regions and the control region. Within the message regions, we find the APPLICATION time. SMF records this time for each transaction in these regions (SRB plus TCB). This is normally the only time which we bill back to the user because it is only at this level that CPU time can be attributed back to an individual transaction. In our site, APPLICATION time and billable time are synonymous. It is instructive to note that the sum of the APPLICATION time which SMF records is slightly less than that recorded by RMF in the message region performance groups.

In a pure IMS environment we call the ratio of APPLICATION time to BUSY time the APPLICATION CAPTURE RATIO. Any fluctuation in this ratio is caused by fluctuations in transaction mix. In a mature system, this capture ratio is stable.

$$\text{APPLICATION CAPTURE RATIO} = \text{APPLICATION}/\text{BUSY} \quad (2)$$

Another important metric is APPLICATION CPU time per transaction. We calculate this for all transactions within an application and not across the entire system.

$$\text{AVERAGE TRANSACTION TIME} = \text{APPLICATION}/\text{TRANSACTION COUNT} \quad (3)$$

We examine not only the stability of the capture ratio but also the stability of the AVERAGE TRANSACTION TIME. In mature applications, the transaction mix is relatively constant and so are these two metrics. There are applications in which the mix is seasonal. We can allow for seasonality if we recognize it. We do not have any applications in which the seasonal change in AVERAGE TRANSACTION TIME is significant. The most variable applications are those which are growing rapidly. These are usually still in the implementation phase, and are picking up new offices and/or new functions. We recommend that capacity planners carefully monitor growth applications, not only to track transaction count but also to see if the transaction mix is as expected. If the transaction mix changes during the implementation of a new application, then the resources which the application ultimately consumes may be considerably different than that forecast.

Later, we will describe how we handle new applications.

For stable applications, we make the assumption that recent behavior of AVERAGE TRANSACTION TIME will be the same out to the forecast horizon. Multiplying this metric by the forecast transaction volume will yield the CPU time for that application. The subscript i indicates an individual application.

$$\text{APPLICATION}_i = \text{TRANSACTION COUNT}_i * \text{AVERAGE TRANSACTION TIME}_i \quad (4)$$

If we repeat calculation for each application, and sum the results, then we arrive at total APPLICATION time.

$$APPLICATION=SUM(TRANSACTION\ COUNT_i*AVERAGE\ TRANSACTION\ TIME_i) \quad (5)$$

Multiplying the total APPLICATION time by the APPLICATION CAPTURE RATIO yields CPU BUSY time.

$$BUSY=APPLICATION/APPLICATION\ CAPTURE\ RATIO \quad (6)$$

This was the number that we started out to calculate. Have we solved the problem? Yes and no. We have just forecast that a CPU will be X% busy in the 4th quarter of next year. How wrong is the forecast? Could the number be X+20%? If X were 83%, then we might have an interesting 4th quarter. We have not solved the problem until we can bound the forecast. If we were forecasting with some time series technique, then statistically it is a simple matter to put bounds on the forecast. We simply tell SAS that we want the 95% confidence limits. When we gather forecasts from users we are not dealing with a time series, we a dealing with a hundred different guesses.

RANDOM VARIABLES

The variables in the above discussion are random variables. Each has an associated frequency distribution. We talk in terms of averages, yet we never see an average day. If we monitor the transaction volume for an application over a period of time, we see a pattern similar to that shown in figure 4. This is a 100 day sample.

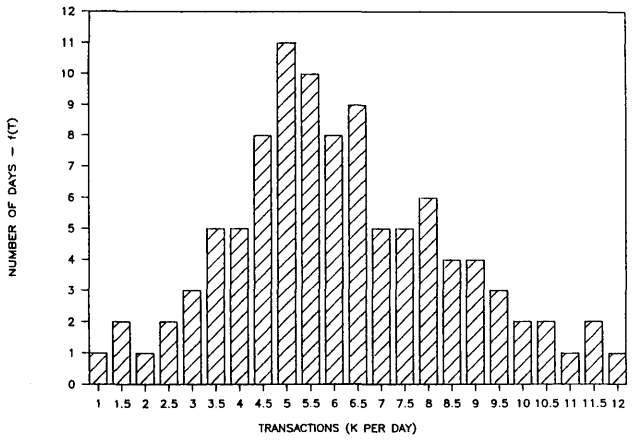

Figure 4. Frequency distribution of transaction arrivals

We observe there were 2 days which saw 2K transactions executed, 11 days at 5K, and 1 day at 12K. Although the average number of transactions run per day was 6K, there was quite a spread. Figure 5 shows the data in an accumulated frequency distribution.

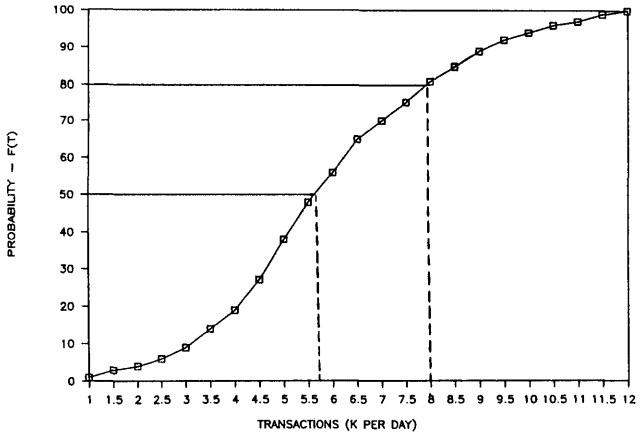

Figure 5. Accumulated frequency distribution

What is most instructive about this curve is that although the average transaction count is 6K per day, there is an 20% probability that the transaction count will exceed 8K. In other words, 1 day in 5 is a heavy day. If there are one hundred different applications running, many of them will have the same heavy day.

If we were to monitor the other variables, we would notice a similar pattern. CPU per transaction, AVERAGE TRANSACTION TIME, fluctuates the same way. We must expect this fluctuation to continue into the future. We track all the key metrics like CPU time per transaction and the various capture ratios over a period time. Quarterly, we calculate their mean and standard deviation. We treat all these measured variables as Gaussian or normal random variables. This is not an assumption. Since we are dealing with statistics calculated from a large number of samples, the Central Limit Theorem assures us that these variables will tend to be normally distributed.

In contrast to the measured variables, we must deal with forecasted numbers from individuals. To account for variability in the forecast, we insist that all forecasts be provided as: lowest possible, most probable, highest possible. As figure 6 demonstrates, a variable defined in this manner is called a triangular random variable. Figure 6 represents the forecast for the application shown in figures 4 and 5. The lowest guess is 3, the most probable 6.6, and the highest guess 12.

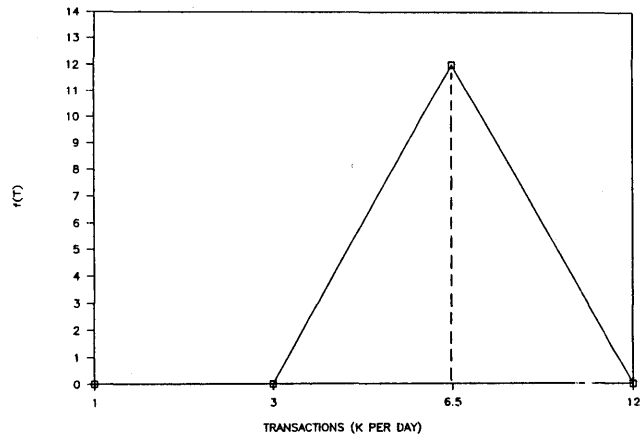

Figure 6. Example of Triangular Random Variable.

Our problem is one of performing the calculations in equations 2 through 6 with random var-

iables. To do this we use a technique called Monte Carlo simulation. The technique was developed by the operations research groups during WWII in England, when they actually threw dice to create random numbers. Later the dice were replaced by tables of random numbers. Now every computer and calculater can quickly and painlessly produce a random number.

Throwing a die extracts a random number between 1 and 6 drawn from a uniform distribution; all results are equally likely. In real world situations, the uniform distribution is quite rare and we require a method of extracting a number from other distributions. In our case, we need random numbers drawn from both normal and triangular distributions. Many different transformations exist to change a uniform random variable into other types. We can program these transformations ourselves, or write the simulator in a language, like SAS, which produces normal or triangular variables on request.

If we want to simulate any given day from the application above, we can ask for a triangular number with the parameters 3, 6.6, 12. If we repeated this calculation 200 times, then we would get a frequency distribution very similar to figure 6. We could simulate figure 4 by asking for 100 normal random variables with a mean of 6 and a standard deviation of 3.5. The essence of a Monte Carlo simulation lies in repeating a calculation many times, inserting a random number drawn from the given frequency distribution in place of the random variable.

Assume we have only two applications, one which has a min, mean, and max TRANSACTION COUNT forecast of (600,1000,1700) and the other of (900,2300,6000). The CPU per transaction, the AVERAGE TRANSACTION TIME, for the first is 20 ms with a standard deviation of 12 and for the second, 35 ms with a standard deviation of 19. Using equation 5, we calculate total APPLICATION TIME by summing the product of TRANSACTION COUNT and AVERAGE TRANSACTION TIME for the two applications. The * in the following equations depicts a random variable.

$$\text{APPLICATION}^* = \text{SUM}(\text{TRANSACTION COUNT}^*_i * \text{AVERAGE TRANSACTION TIME}^*_i) \quad (5a)$$

We get TRANSACTION COUNT for the first application from a triangular distribution with the parameters 600,1000,1700 and the AVERAGE TRANSACTION TIME from a normal distribution with mean 20 and standard deviation 19. We follow the same procedure for the second application. Figure 7 shows a sample run of 5 iterations.

Application A			Application B			
Trans Volume	CPU/ Trans	Appl. Time	Trans Volume	CPU/ Trans	Appl. Time	Total Time
1200	17	20400	1123	32	35936	56336
921	13	11973	2670	41	109470	121443
1403	24	33672	2354	29	68266	101938
753	29	21837	4200	37	155400	177237
1298	22	28566	3521	30	105630	134186
						118228 Average

Figure 7. Sample Monte Carlo Output

If we repeated this calculation 100 times, we would get an output distribution for total APPLICATION TIME similar to that shown in figures 4 and 5. In our shop, we iterate 200 times such that for each forecast period we end up with 200 random days within each period. By dividing APPLICATION TIME by the APPLICATION CAPTURE RATIO we get 200 values for CPU BUSY time. We reduce these 200 days by calculating the key statistical parameters, mean, standard deviation, 95th percentile, etc..

Assume that the threshold busyness for a dedicated IMS environment is 80%. In other words, we plan on upgrading a processor whenever it exceeds this average threshold. We can arrive at this threshold by experience or by modelling. The idea being that when the CPU is busier than 80% on the average then at peak periods response will deteriorate. Assume for a moment that we do not use the Monte Carlo technique and rather do a straight calculation using equations 2 through 5 and the most probable forecast value. Further assume that this calculation yields a forecast for average CPU utilization at 75%. Since this is well below the threshold, we inform our managers that they need not be consider an upgrade within the forecast horizon. If the forecast is low, then there will be some rude surprises.

Now lets do the same calculation using the Monte Carlo technique. We should get the same answer, 75%. In addition, however, we get a probability distribution which shows that, although the average is 75%, there is a 40% probability that the CPU utilization will exceed 80%, and a 10% probability that it will exceed 90%. We can only achieve this result, the probability distribution of processor utilization, by using a simulation. Capacity planners must give this critical information to management and they must use it as the basis of resource planning.

For applications which are still in the planning stage, it is not possible to measure any of the metrics which are essential to the forecast. In these cases, we have developed the concept of the look-a-like application. Developers inform us of an application which is similar to the one which they are working on. They give us their TRANSACTION COUNT forecasts and we measure the CPU time per transaction from the look-a-like. In a shop which has many applications and different transactions, finding a look-a-like is not a major problem.

EXTENSIONS

Let us now consider a more complex configuration. Suppose that we run some DB2 and some batch on a processors and that all the workloads are growing. Figure 8 below shows the CPU measurement diagram for this.

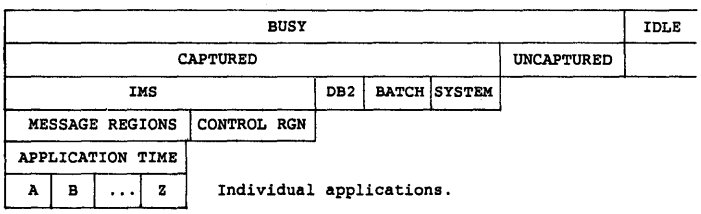

Figure 8. Schematic of time recording on mixed mode machine.

We calculate APPLICATION TIME exactly as equation 3. The rest is different. In equation 7 we calculate a ratio, the IMS RATIO, which is APPLICATION TIME divided by IMS TIME (the sum of the CPU time in all the IMS performance groups). We observe this ratio over time and, as before, measure the parameters of its distribution. In the simulation calculations, we work backwards and use this ratio to arrive at IMS TIME.

```
IMS RATIO = APPLICATION TIME / IMS TIME                    (7)
IMS TIME" = APPLICATION TIME" / IMS RATIO"                 (8)
```

We are now in the third layer from the top in figure 8. We will assume that techniques exist to forecast DB2, BATCH, and SYSTEM CPU time at this level. For example, one possible way would be to forecast user connect time and track CPU time per connect hour. We can then forecast DB2 time by:

```
DB2 TIME"=Forecast CONNECT time" * CPU time per connect hour"   (9)
```

We nest this calculation in a Monte Carlo program similar to the way we develop IMS time. Lets assume that the BATCH time and SYSTEM times are forecast by a trend line, and available to the program.

At this point we must calculate capture ratios. The UNCAPTURED time in figure 8 is not constant nor can we distribute it proportionately across the 4 subsystems. In this environment, the following calculation is NOT correct.

```
BUSY=(CAPTURED + UNCAPTURED)
    =CONSTANT * CAPTURED
    =CONSTANT * (IMS + DB2 + BATCH + SYSTEM)
```

If this were true, we would have a much simpler problem. (Note that CONSTANT is equal to 1/SYSTEM CAPTURE RATIO in equation 1.) Unfortunately, the system uses UNCAPTURED time in differing amounts for each of the four subsysems. In other words, each of the subsytems has a different capture ratio. The following calculation IS correct.

```
BUSY=(CAPTURED + UNCAPTURED)
    =CONSTANT * CAPTURED
    =BETA1*IMS + BETA2*DB2 + BETA3*BATCH + BETA4*SYSTEM        (10)
```

The values beginning with BETA are constants. Continuing the same convention, we call the reciprocal of the BETA, a capture ratio. The BETAs, as shown in equation 10 can only be calculated by multiple regression. Performing this procedure is relatively simple with SAS. Now that we have all the data required, we can forecast CPU utilization by putting equation 10 into the simulator. We treat the BETA variables as normal random variables. The regression procedure which calculates the BETA values for us also provides the standard deviations. In the regression, the standard error of the parameter estimates is the standard deviation of the capture ratios.

```
BUSY"=BETA1*IMS" + BETA2*DB2" + BETA3*BATCH" + BETA4*SYSTEM"   (10a)
```

SENSITIVITY AND "WHAT-IF" ANALYSIS

Let us assume a more complicated system has 5 different workloads: IMS, IDMS, DB2, BATCH, and SYSTEM (CICS and TSO are on another system!). We have a detailed Monte Carlo model of this system which uses equations similar to equations 7 through 10 above. In our analysis of the output of the 200 iterations of the simulation we can calculate how much the result varied for a 10% change in each of the input variables. This is a sensitivity analysis and it may look something like this:

```
a 10% change in "IMS application X"  generates a  4% change in "BUSY"
a 10% change in "IMS application Y"  generates a  8% change in "BUSY"
a 10% change in "BATCH"              generates a  2% change in "BUSY"
a 10% change in "IDMS application Z" generates a 10% change in "BUSY"
                        .                          .
                        .                          .
                        .                          .
a 10% change in "DB2 connect time"   generates a 22% change in "BUSY"
```

Our whole exercise was most sensitive to the variation in "DB2 connect time". This fact will become extremely valuable for management control.

"What If" we added another IMS application. We insert the forecast transaction volume and look-a-like application as before. Perhaps we would increase the standard deviation of the different variables to take into account our lack of certainty.

Because of the way we have structured this model, it is easy to modify parts of it and rerun. As such, "what if?" analysis is very easy. To "what if?" we increased the size of the CPU, we would simply multiply all the CPU factors by the constant which relates the size differences. To "what if?" we moved some applications to another system, we change the system identification field in the input data and the forecast is automatically inserted into that systems forecast.

An evolution to the system which we are currently working on is that of extending the forecasts out two years beyond the horizons that the developers are willing to forecast. We are designing this enhancement with time series and by modeling expert business analyst guesses. We are also currently adding IDMS to the forecasts and the simulations.

The technique is not without its problems. The shrinking application development window implies that we may miss an entire application. Our developers forecast only those applications which they are working on. It is possible for an application to be written and implemented within the forecast horizon and yet be unknown to all developers at forecast time. The inability of a developer to forecast applications which he is unaware of creates a flattening of the forecast curve out near the horizon. This flattening can be extremely misleading. From figure 9 we see that the forecast line can cross our planning boundary anywhere during 5 quarters. This effect can be minimized by keeping the forecast horizon the same length as the development window.

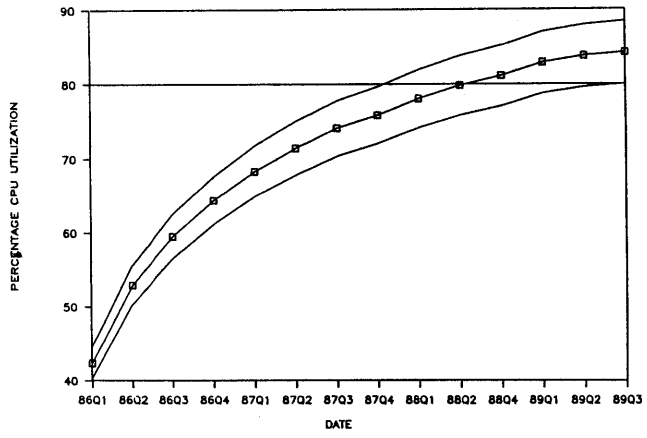

Figure 9. Sample forecast showing flattening effect.

CONCLUSION

We have been using this procedure for two years and we feel that it's greatest strength lies in it's ability to output probabilities of percent utilization. The increased amount of information which goes into the forecast makes possible the increased amount of information which it yields. The additional work can be automated and is worth the effort. The high credibility afforded to the results is due to the involvement of the users and developers and the amount of work they put into their input. Good forecasts are only produced with good data and good analysis. We recommend that other capacity planning groups adopt this technique for any forecast which is comprised of guesses from developers and users. It's flexibility and accuracy have brought it wide management acceptance.

MODELLING OF A PRODUCTION IMS SYSTEM UNDER A MULTI-FUNCTION PROCESSING ARCHITECTURE

Dale Gilbert
Lomas & Nettleton Information Systems

ABSTRACT

IMS production systems at Lomas & Nettleton Information Systems (LNIS) utilize the facilities of the Future Systems Architecture (FSA). The FSA is an umbrella structure which provides access to terminal and data base functions for application programs without the programmer being cognizant of specific parameters or syntax. Under the FSA each IMS transaction may process many different types of requests based upon the "function code" submitted. Multiple instruction paths may exist within the same module making accurate transaction characterization difficult.

Analytic models of the FSA and production IMS systems are constructed using detailed analysis of trace and logging information. These models are used as a basis for forecasting future processing requirements for new applications under development.

INTRODUCTION

An architecture within IMS or other environmental software is used to centralize functions or operations common to other related applications in single area or set of programs. In addition such functions as uniformity of logon procedures across applications and security checking at a transaction level may be implemented within the architecture.

There are two general approaches to architecture design illustrated in Figure 1. A horizontal approach places the architecture components at the same level as the application programs. The programs are called directly from the environmental software and communicate with the architecture components and other applications through architecture calls. A vertical structure or umbrella approach places the architecture components between the environmental software and the application programs. The programs are called by means of program-to-program message switching within the architecture. This paper is concerned with the latter architecture currently in production at LNIS. A future use of this procedure will be to evaluate a horizontal implementation of the architecture.

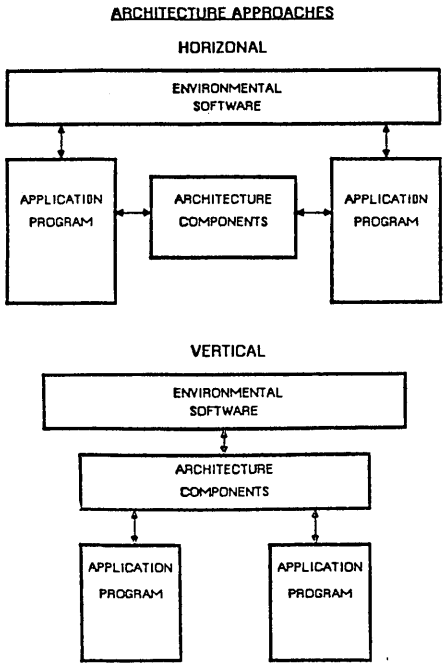

Figure 1. Alternative Approaches to IMS Architecture.

The vertical architecture has the following processing flow. When a terminal message is received by IMS it is queued against the Message Control Facility (MCF). The MCF program then analyzes the message based on flags/codes that exist in the architecture Scratch Pad Area (SPA) for the particular terminal and may select one of four options:

1) Pass the message to an application program. The appropriate driver associated with the targeted application program is selected based upon information contained within the current function code. The new function code information is assembled and a message switch is then made to the appropriate driver program with the incoming message appended.

2) Process the message as an MCF command. MCF calls the associated routine to process the request and returns an informational message to the terminal.

3) Process the message as a function code switch. MCF checks the access security of the user against the requested function code and creates a message switch to the appropriate driver/application program.

4) Process an unsolicited message. MCF interrupts the current conversation with the user and displays the message. Depressing 'Enter' causes MCF to continue the conversation.

A driver is a control program which selects the application to process a given message. The driver appears to IMS as an application program with its own Program Specification Block (PSB) and the corresponding Program Communication Blocks (PCBs). In turn a specified number of application programs are associated with each driver. These application programs are selected by function code and do not appear at the environmental software (IMS) level. The databases (DBDs) for each application must be defined at the driver level.

When a message is switched to a driver, the architecture SPA is again analyzed for path information and the corresponding application program called to service the message. Upon return, an interrogation of the architecture SPA determines whether 1) a second program within this driver, 2) an additional message switch, or 3) a response output to the user is required. When a message switch is required the cycle is repeated for the second driver. The output message ends the cycle until a new input message is received.

When a terminal message is received by IMS it is queued against a driver's transaction code. The driver then analyzes the Request Entry Line portion of the message to determine if a command or a function switch has been

entered. If the message is a command the associated routine is called to process the request and an informational message returned to the terminal. If the message is a function code switch then a message switch is made to the appropriate driver and the application program indicated by the function code.

Therefore, the Future Systems Architecture may be considered a multi-function processing architecture in which a single 'transaction' module may process many different types of requests based upon the function code submitted. Multiple instruction execution paths may be used within the same module.

OBJECTIVE

LNIS has and is developing a number of IMS applications planned to execute under the Future Systems Architecture described above. Given the projected magnitude of applications under development and expected business growth, a need exists to determine if service levels can be met and what are the hardware requirements to deliver the service levels.

The approach decided upon was to model in detail existing applications that execute under the architecture and from this effort develop procedures to aid in modelling the developmental applications.

SYSTEM DESCRIPTION

The host hardware environment consisted of an IBM 3090-400 processor and a combination of 3380's and 3380E's as primary I/O devices. The initial modelling effort took place with an IBM 3090-200 which was approaching its capacity in terms of the total workload. The difference in the processors provided additional model verification.

INSTRUMENTATION

The initial step was to identify the characteristics of each function code instruction path. A user executed a script based on the function codes belonging to the target application within the IMS test region. During the user session the IMS/VS DC Monitor was turned on to capture the DL/I calls. In addition the IMS log for the same time period was captured. The log included records from the IMS Measurement Facility (IMF). Each function code submitted during the session had the same driver, e.g., the transactions identified by the IMS log and IMF data were all the same name. However the sequence of execution given by the ITASK number within each message region of the records was sufficient to associate each function code with its resource consumption and its DL/I call pattern as shown in Figure 2. The DC Mon records are sorted by message region, ITASK number, and time stamp. The ITASK number is assigned by the IMS control region in order that IMS resources become available to processing programs and thus is the order of execution of the DL/I calls within the transaction.

The IMF data identifies the drivers (programs) called by the function code from within the architecture by the alternate PCB created by the program-to-program message switch. The alternate PCB name is the same as the driver name. The initial transaction and the subsequent driver invocation both have the same arrival time stamp. When the data is sorted by arrival time stamp, message region, and user identification the message switch transactions will be paired. The architecture transaction that generated the function code transaction sequence of Figure 2 is shown in Figure 3.

The DC Monitor data used in this analysis are the type 10 and type 60 records. The type 10 records are generated when a message scheduling event is started. These records identify the transaction and provide the initial time stamp and message region. The type 60 records are generated by DL/I calls and provide the bulk of the information. The type 60 records, when sorted by ITASK, reveal the DL/I call pattern of that transaction. The DL/I call is identified by the PCB name, the type of call, the segment name being retrieved, and the return status of the call. In addition, if any physical I/O's are made, the DBD name of the database and the time spent in IWAIT are recorded.

The paired transactions from the IMS log and IMF data can be interleaved with the DC Mon data by the transaction name, message region, and the successive time stamps of each source. The resulting data contain a complete picture of the architecture application interface. The architecture overhead consists of a transaction that is paired with each unique application transaction. The application can be modeled and evaluated separately from the architecture overhead. The overhead can then be added to give a complete performance picture.

The remaining information required for the model was the identification of the function code that the driver represented. Each driver is capable of multiple tasks according to a particular function code definition. Modelling at the driver level would not permit sufficient insight to generalize the model components and extend them to future applications. Some function codes within the drivers are peculiar to applications and must be identified.

Upon examination of the IMS log data it was discovered that the function code was carried in the type 01 and type 03 records. These records contain the screen transmission records in which the current date is followed by the function code the operator entered. Thus by using the time stamp of the log record to match with the IMF transaction records and the DC Monitor trace the transaction can be identified at the function code level. It is also true that this procedure can be extended to the production IMS environment in a strictly passive mode; no hooks are required to be placed in a production system. Using the same procedure within the production IMS system also would give the frequency of occurence of each function code, a necessary quantity to calibrate the model.

DATA COLLECTION

A peak period of transaction activity was selected for data collection. The sampling interval was limited to eight minutes due to the volume of data collected and the degredation upon system performance produced by DC Monitor. The eight minute interval produced 76,000 DL/I calls from about 1100 recorded transactions.

The type 60 DC Monitor records provided the detailed description of each DL/I call. The type 60 record contains the PCB name, DL/I function call, segment name, segment level, return code status, and any I/O wait due to a physical I/O. If no IWAIT trailer is present then no physical I/O took place. The number of IWAIT trailers in the record is then the number of physical I/O's per DL/I call. Additionally, when an IWAIT occurs the DBDNAME is carried in the trailer record along with the IWAIT time to complete the I/O.

When the type 60 record is combined with the type 10 record by ITASK number the PSB name is obtained. The PSB name is the same as the driver or transaction name. Combining again, this time with the IMF data by message region, transaction, and time stamp gives a complete transaction description down to the DL/I call pattern.

An additional benefit from looking at the detail type 60 records is the breakout of I/O to secondary indices. The IWAITS per DL/I call due to secondary index I/O is lost in the summarization process of the DC Monitor Call Summary Report. In the detail record the IWAIT is identified by the DBD name of the secondary index database

permitting the physical I/O's of the model to be directed against the correct database with the same PCB.

The collected data is now sufficient to build modules representing each of transactions/function codes occuring during the trace period. In summary the data consists of:

1) Driver and function code
2) Database being accessed
3) DL/I call sequence
4) DL/I call type
5) CPU time per function code use
6) I/O time per DL/I call
7) Physical I/O's per DL/I call
8) Secondary index use per DL/I call

The remaining data required to parameterize a DL/I call are the database type, organization, and placement. The task was simplified since all application database organizations under the FS architecture are VSAM. Dataset placement is an important consideration in IMS performance analysis and in its impact upon system performance. The data collection effort identified all active databases from their DBD name. The Database Administration function maintains a VSAM definition file in which each DBD name is associated with its cataloged dataset name, organization, block size, and its volume residency. Due to ocassional dataset movements for performance or other reasons, this definition file is read and a database catalog built as a module of the system description file.

MODEL CONSTRUCTION

Modules of each function code can be constructed. A particular function code can be represented by summarizing the monitor data by type and frequency of DL/I call. This will give an accurate representation of each function code but the summarization process loses the call pattern. The call pattern is useful for insights into program logic and to maintain a continuity with the design process - the end product.

Figure 2 shows a sequence of DL/I calls from a specific function code (DMI). When the monitor data is sorted by ITASK number for each function code and transaction with each message region, the DL/I call sequence of the original IMS transaction is obtained.

All transactions using the architecture begin their database call sequence with an I/O to the FSA spa to record the timestamp and other information the programmer sees fit to maintain. Following the call to the spa the sequence of calls belonging to the function code appear. The number of physical I/O's per transactions is the single most important component of response time. In the monitor data any time an I/O is performed the DBD name is recorded. The summarization process accummulates the I/O's for each database. In the example in Figure 2 the impact of using secondary indices to access data is recorded. The DL/I call identified by ITASK number 3F3AE8 obtains a loan number from the mortgage loan database MTGP001D. The next ITASK number (3F3AED) is repeated twice. The first line represents the I/O to get the required information from the Funds database. The next occurrence of the ITASK number contains the I/O required for the secondary indices. These I/O's are recorded by the DC Monitor to the same ITASK record. Three physical I/O's are required to obtain the necessary references to identify the desired record in the Funds database.

Another typical sequence of calls is shown in the next sequence beginning with ITASK 3F3B00. Calls are made to a database containing keys to another database. The initial call (a Get Unique) to the key database (TR2Y001I) requires two physical I/O's. An alternating sequence of DL/I calls then begins using the key information to identify the requested record in the master database (TR2P001D). After the initial GU call to the key database the I/O is performed using GN (Get Next) requiring, in most cases, no physical I/O (the record is already in the buffer). A physical I/O occurs with the GN when the record is not in the buffer and must be retrieved from DASD. In this sequence each call to the master database requires a GU and a corresponding physical I/O. The sequence ends when a status code of GE is returned indicating the root level has been reached and no additional information exists.

The remaining calls within this transaction interact with the database DLMPHSTD. An initial GU requiring one physical I/O is made to DLMPHSTD to obtain the level one segment DLMHMTG, a delinquent mortgage. A search is then made through the level two segments with GNP (Get Next within Parent) requiring no physical I/O until a level three segment is obtained (DLMQAGN). Following the segment DLMPQAGN call are two Get Unique's to the PMF tables. The PMF tables or Parameter Management Facility contain the format of the segment and enable the calling program to decode the segment into valid information. This technique makes the application less dependent upon specialized code but at a cost of one physical I/O per decoded segment. The status code of GE is returned whenever the segment level reached in the search increases, e.g., a GNP returns another parent rather than a child of the current parent.

Once the desired record is found additional information is collected from other databases and a screen is filled. At the conclusion of the transaction a replace (REPL) is made to the FSA spa and calls made to I/O PCB.

The transaction of Figure 2 requires 38 physical I/O's to complete the DL/I call sequence. At a nominal 3380 service time of 25 milliseconds per access the I/O component of the response time of this transaction should be 0.95 seconds.

One problem arising in looking at individual transaction call patterns is that many of the calls are database dependent. In the previous example the number of calls for a twin chain search depends upon the number of individual segments within a parent. If data from a number of such transactions are collected in the monitor interval an overall average transaction call pattern can be obtained.

Figure 4 shows the relative frequence of occurrence of function code use within driver DLMP100 using the IMS log type 03 records. The total hourly arrival rate is represented by the driver. The remaining function codes are the components of the driver, i.e., the sum of the arrival rates of the function code equals that of the driver. These values translate directly into model transaction arrival rates. The total CPU utilization of the IMS application is shown in Figure 5. Again the utilization of the driver is the sum of the utilizations of the function codes called by the driver.

Figure 6 shows the response times for these function codes from the IMF data when the individual transactions are identified from the IMS log data. The CPU consumption per function code use is computed from the data represented in Figure 4 and 5 and is shown in Figure 7.

Due to the volume of trace data a procedure was developed to create the simulated DL/I calls in a format necessary to represent each function code call as an input to an analytic model which described the internal IMS 1.3 pathlengths. The DL/I call patterns are generated using the processed DC Mon trace and IMS log data. The data were summarized by function code and frequency of occurrence of each function code. The modules developed in this manner could be referenced from more general workload descriptions within the model. Additionally, the performance of the driver modeled as a composite of function codes could be compared to standard reported measurements.

Figure 8 shows the modelled results of driver response broken into its components of CPU, I/O, and memory. Breaking the driver into its function codes gives the results in Figure 9. A more detailed look at response time as calculated from the model is shown in Figure 10. Each function code's residency time is computed at each of the system components.

A still more detailed output is shown in Figure 11 at the device level. The utilization of a particular device can be broken into database activity. This simplifies analysis of response time problems resulting from database contention within the driver and architecture applications.

The detailed output at the device level was useful during model calibration. The I/O devices were all 3380 D & E's with an estimated value for average seek time of 16 milliseconds. The response time component due to the CPU was within acceptable limits when comparing model output with monitor output. However, the I/O component was significantly higher for many of the devices. Using a tool designed to measure DASD performance provided actual seek times for each device within the model. The seek times ranged from 4 to 10 milliseconds for the production IMS packs which included both databases and program libraries.

The IMS production databases are subject to frequent tuning efforts to ensure optimum database performance (response time) through minimum arm movement. Including these estimates into the model produced response times within acceptable limits.

The resulting model can be evaluated against projected changes in both the architecture and existing applications. As demonstrated earlier the architecture transactions are broken out separately from the application and proposed changes can be implemented independently of or in conjunction with each other. Models of proposed applications similar to the application in this study can be constructed using the modules created from the detailed DL/I trace data. As shown in Figure 12 the model output reflects both the architecture and the application effects when proposed transaction growth is included.

The response times from various level of IMS activity were compared to the modelled results in Figure 13. During the period of model construction the processor was upgraded from an IBM 3090-200 to an IBM 3090-400. The response times from the model 400 activity show a very good agreement with reported values. The response data obtained from the Model 200 environment reflected the capacity limits that not only IMS was experiencing but also the remaining 80% of the workload. The IMS application and, as a result, the output reflects a dedicated processor running at a 20% busy level. To account for the elongated response times observed with the Model 200 a performance model of the complete system is required. The model of the IMS workload can be incorporated into a total workload description and a truer picture of service level performance obtained.

CONCLUSIONS

A procedure for evaluating the performance of existing IMS applications that conform to a multi-function processing architecture umbrella has been outlined. The procedure uses a number of generally available IMS performance monitor sources to produce modules representative of individual function codes that exist under the architecture and are not readily available from standard reporting procedures. The modules are developed both to model the architecture effects and to provide an interface with new application designers. Estimates of the performance and resource requirements of applications under development can be obtained by constructing analytical models using similar type modules with new database and system descriptions. The entire IMS production workload can then be evaluated using a higher level analytic model. The complete workload can be analyzed in terms of response times and throughput (transaction processing) in a resource contention environment by using a performance model with the modelled workload included. The end result should be a true picture of expected application performance in a specific processing configuration.

MEMORY MANAGEMENT FOR LARGE IBM SYSTEMS

Michael R. Lee
Candle Corporation

ABSTRACT

Recent hardware offerings from major processor vendors are providing an amazing increase in real storage capacities. For most users of these processors, this increase provides much needed relief for overloaded paging subsystems. For those who constantly push the limits of hardware technology, however, these larger memories are still causing problems with application performance. This paper will explore some of the recent trends in increased real storage capacities together with some of the other trends - specifically expanded storage, and discuss a coordinated analysis methodology which may be used to "tune" the available memories for optimum performance and capacity.

INTRODUCTION

Memory management in the Multiple Virtual Storage (MVS) environment has been a challenge for system programmers and capacity planners for many years. Typical approaches to memory management center around controlling paging and swapping through use of storage isolation and appropriate Installation Performance Specification (IPS) definitions of performance groups and domains. With the arrival of IBM 3090 processors and Expanded Storage, the challenge of effective memory management has become even more difficult.

This paper presents a memory management methodology that has proven to be useful in a number of MVS installations in the USA. The topics discussed include: Hierarchy of memory management, System Resources Manager (SRM) memory control philosophy, Dynamic memory controls Categories of memory, Real memory management, Expanded memory management, and Auxiliary memory management.

HIERARCHY OF MEMORY MANAGEMENT

In a virtual storage environment, a task must have currently executing instructions in a frame of real memory to enable the CPU instruction fetch hardware to access the instruction to be executed. If the instruction to execute is not in a real storage frame, a page-fault is recognized triggering the page-in process. The specific page must be moved from an auxiliary storage location (auxiliary storage or expanded storage) into an assigned frame of real storage. From a task performance viewpoint, page-fault processing is non-productive time for the task because it must wait for the page to be retrieved from auxiliary storage. Too many page-faults for a task mean too much time waiting for page I/O and not enough time executing application program instructions.

The number of pages for an application which must be in real storage to prevent page-in waits from becoming a performance bottleneck can be called the "critical working-set". Maintaining or protecting the critical working-set for active tasks is the overall objective of memory management.

Unfortunately, real storage is a finite resource and is shared among all active tasks. Paging is a result of multiple tasks competing for a limited pool of real storage frames. Some tasks are more important than other tasks. The important tasks are favored or preferred both in access to/ownership of real storage frames and in dispatching priority sequence.

Memory management requires careful planning and periodic monitoring. Planning includes selection of appropriate IPS parameters to allow enough separation of work loads among performance groups, selection of appropriate domain constraints (MPL boundaries), and dispatching priorities. Planning also includes design of the paging subsystem (even if expanded storage is present).

Periodic monitoring is necessary to observe possible shifts in work load mix. Work load mix variations may result in an increase or decrease in average system wide MPL. Changes in MPL indicate there are more or fewer address spaces competing for available real storage frames. Failure to identify these shifts in work load patterns may result in overloads of domains or possibly artificial constraint. The domain definition process should include an analysis of the storage/paging requirements for the work load based upon expected MPL levels. When this level is determined, appropriate constraint values for the domain are assigned to avoid unnecessary memory overload or underload.

Memory management must be structured in an hierarchical fashion. This philosophy includes consideration that the load on a modern MVS system will fluctuate dramatically during the processing day.

The purpose of memory management is to keep critical application pages in real storage and if necessary, remove pages for non-critical applications. Thus as contention for real frames increases, stealing will occur from low priority tasks.

The actual stealing of frames is performed by RSM (Real Storage Manager), but SRM (System Resources Manager) determines which address space(s) will have frames stolen. SRM also determines how many frames are stolen from each candidate address space. The stealing process may be altered by specification of storage isolation for a performance group. The performance groups are defined in IEAIPSnn.

If real storage frame contention becomes critical, SRM will consider swapping out some tasks in low priority domains. This event triggered swapping occurs under control of SRM and is influenced by user selected options set in IEAOPTnn. The determination of low priority

is made by SRM through an analysis of the contention indices for all domains.

Paging is not bad in and of itself - paging is what makes virtual storage systems work. Most programs have very definite instruction reference patterns. The subset of pages within an address space that correspond with the reference pattern are the only pages that need be resident in real storage.

The trick is to keep the "necessary" pages in storage for active address spaces and to remove idle or inactive pages to make room for more active pages. Unfortunately, the inactive pages that have been removed from real storage frames may and often are re-referenced by the owning address space. Page-delay time is the time required to determine the location of a page (in expanded storage or on auxiliary storage) and to relocate it back into a real storage frame. Page-delay time now becomes a significant component in the performance of the address space, especially if the address space is processing a trivial interactive request.

Tuning choices involve selection of parameters to tell SRM how to manage memory. You must determine how much paging is acceptable for a particular address space (e.g. CICS, IMS, TSO, etc.) and set up a memory management philosophy that will keep paging and thus performance for key applications within acceptable service level bounds.

The tuning choices available are: storage isolation, MPL constraints for domains, overall system MPL, UIC level, page-fault rate, demand paging rate, and others. These options are discussed later in this paper.

SRM MEMORY CONTROL PHILOSOPHY

Many people expect SRM to bail them out of a performance problem resulting from ineffective option choices (or default parameter values).

SRM is just a group of programs that attempt to deal with resource overload situations such as CPU 101% busy, high paging rate, ASM slot shortage, low UIC, etc. SRM is a complex component that includes many algorithms.

The algorithms are influenced by option selections in IEAOPT and IEAIPS. Depending upon which options are selected and the values used, SRM control can be described as absolute or dynamic.

Absolute controls are analogous to a sledge hammer. The system runs unrestricted up to the point of overload, then SRM must take drastic measures to reduce the load demand (i.e. swap out everybody I can). The system then thrashes by trying to exchange swap the active users with the swapped users.

Dynamic controls are analogous to screw drivers. Dynamic controls are fine tuning mechanisms that allow gradual adjustment of the MPL to reduce thrashing and improve throughput and response time.

Absolute memory controls are the outside bounds controlling the number of tasks allowed to compete for system resources. The MVS MAXUSER parameter defines the absolute maximum number of address spaces that MVS may create (started tasks + TSO + batch). MAXUSER parameter sets the maximum number of TSO address spaces that MVS may create.

Once an address space is created, access to real storage frames (and thus the CPU) is controlled through the MPL. There are two levels of MPL to consider. First is "system wide MPL" which represents all address spaces now in real storage and competing for resources. Secong is "domain MPL" which represents the current MPL for a specific domain. Each domain has a domain MPL value. Each domain's MPL value is adjusted by SRM based upon the system wide MPL and the contention index for each domain.

MPL adjustment depends upon the IPS options selected for the performance group (i.e. the domain to which an address space is assigned - which can change for multiple period performance groups).

The domain is the primary point of control over a particular work load by limiting how many address spaces of this type are active at a time. Constraints for a domain are evaluated with respect to the memory, CPU, and I/O requirements of the work load(s) running within this domain.

IEAOPTnn parameters are used to provide SRM with performance boundaries for critical system contention indicators and thus affect system-wide MPL based upon SRM's observations of these indicators. The IEAOPT parameters that affect MPL adjustment are listed below:

RCCPTRT: Page-fault rate threshold
RCCUICT: UIC - measure of how active frames are
RCCASMT: ASM queue length
PAGERT1: Demand page rate threshold for 1 CPU on-line (also applies to more than 2 CPUs)
PAGERT2: Demand page rate threshold 2 CPUs on-line

Work flow through an MVS system varies greatly during the processing day. There are times when real memory and CPU become overloaded. The memory management question now becomes: "how should SRM deal with this situation?"

RCCPTRT and RCCUICT provide a mechanism for establishing the bounds of "acceptable" real storage contention as measured by UIC and page-fault rate. If UIC or page-fault rate exceed the upper bounds, system wide MPL will be reduced. Of course, this means SRM must now select the domain with the lowest contention index that is not at its minimum constraint and swap an address space out. Clearly, this action will reduce the number of competing address spaces and thus should reduce storage contention.

RCCASMT, PAGERT1, and PAGERT2 are very volatile numbers. Using these values for MPL adjustment can lead to swap-thrashing if the values used are not carefully selected and monitored. In most cases, these parameters are set to very high values to eliminate their influence on MPL adjustment.

Adjusting MPL based upon UIC and page-fault rate is usually a sound approach to MPL management. This is because these measures tend to be fairly consistent values over time thus avoiding radical changes in MPL due to temporary spurts of paging activity.

NOTE for 3090 expanded storage users: Be aware that demand paging done to expanded storage is not included in paging statistics and is not included when SRM checks these OPT thresholds. Only pages sent directly to auxiliary storage and page reclaims are counted.

DYNAMIC MEMORY CONTROLS

The objective of dynamic memory management is to select a combination of OPT/IPS parameters which will allow SRM to protect response critical tasks to the point where service level objectives are being met.

Selecting options which allow SRM to adjust the degree of protection to that required to meet service level objectives helps avoid needlessly tying up memory resources for a task that does not need them. A good example of the dynamic management approach is to specify the private-page-rate parameter (PPGRT/PPGRTR) when using storage isolation (PWSS).

Of course, one must realize that there are always exceptions to the rule and as such, it may be necessary to "waste" some amount of storage in order to provide an address space with sociopathic tendencies enough real storage resource to meet service level objectives (usually CICS, DB2, IMS etc.).

CATEGORIES OF MEMORY

There are three categories of memory addressed in this paper. First is real storage. Second is expanded storage and third is auxiliary storage.

As processor speeds have increased, the need for more memory has increased. This relationship exists because instructions must be in real storage before the processor can execute them. A faster processor can execute a series of instructions at a given speed, but most programs perform some type of I/O operation during their processing. I/O processing is extremely slow when compared to CPU instruction cycle times (e.g. if one nano-second equaled one second, one milli-second would equal 11.5 days). This time differential requires a fairly large queue of work awaiting execution to keep the CPU(s) busy - this means a fairly large MPL is required - and large MPLs require large amounts of real storage.

Expanded storage provides a mechanism to increase the availability of real storage frames (thus allowing even higher MPLs) by requiring fewer pages to be kept in real frames. If a stolen page is re-referenced, it can be quickly retrieved from expanded storage (on non-expanded storage processors, these page references resulted in comparatively slow page data set I/Os).

Auxiliary storage has been around for many years now and has not changed much in physical implementation (i.e. page data sets required, swap data sets optional). There have been some interesting changes in management algorithms however. Changes such as the contiguous slot algorithm (block paging capability), suspend-resume channel program, etc. greatly improve the efficiency of paging, but the most significant shortcoming still exists and that is the time required to do physical I/O to a rotating disk device.

REAL MEMORY MANAGEMENT

The objective of real memory management is to keep active pages in real storage frames as a result of careful MPL management and a reasonable demand paging rate.

Absolute real memory controls are rigid and inflexible. Three examples of absolute controls are: V=R, Page-fixing, and Non-swappable. Once set, these controls provide no mechanism for SRM to adjust memory allocations based upon the demand for real storage frames.

Dynamic real memory controls are flexible (within user defined bounds) allowing SRM to dynamically adjust memory allocations based upon demand for real storage frames. Logical swap is an example of a dynamic real memory control.

Dynamic controls are effective if used properly, but are expensive if abused. Inappropriate or excessive use of dynamic controls can result in both ineffective resource utilization and limited resource availability for other address spaces (i.e. you may improve the targeted application but degrade every other address space in the process).

Page stealing/faulting is one of the most serious performance problems faced by large interactive address spaces. Page stealing is serious because should the address space re-reference the stolen page, a page-fault will occur which will stop the task's TCB. If the TCB suffering the page-fault is the primary or major work TCB (as in CICS or TSO or IMS control region), all processing stops for that application and cannot resume until the referenced page is returned to a real storage frame.

The simplest method to prevent paging is to run V=R mode. This is no longer practical considering the large MPLs run on modern processors. The next method is to affect the page stealing process through SRM parameter options such as storage isolation.

NOTE: For 3090 expanded storage users: Storage isolation no longer guarantees a specific resident working set (real frame working set). Storage isolation now computes the number of real frames occupied and adds the number of expanded frames occupied to arrive at "working set size" to which the storage isolation target working set size is compared. Expanded storage frames that exceed the target working set are then eligible for migration to auxiliary storage should expanded storage become constrained.

LOGICAL SWAP

Using IEAOPT parameters, the system programmer can provide SRM with a lower and upper bound for each of the IEAOPT parameters affecting logical swap. Logical swap is expensive in that idle address spaces may continue occupying real storage frames with the expectation that the logically swapped address space will enjoy improved response time.

Logical swap demands real storage and if logical swap is permitted during periods of severe real frame contention, a few address spaces will see improved response times but will likely result in higher demand paging rates for all other address spaces. The effect on other address spaces may be acceptable in a large TSO environment where TSO is the primary application.

Logical swap is most effective if implemented as a dynamic facility. SRM may adjust the duration of the logical swap based upon real storage frame contention. If contention is high, the duration of logical swap will be short (in fact, SRM may be allowed to "shut off" logical swap through selection of appropriate IEAOPT parameters). If contention is low, the duration of logical swap will be longer. The IEAOPTxx parameters used to control logical swap are listed below:

LSCTMTE LOW and HIGH Think Time Thresholds (SECONDS)
LSCTUCT LOW and HIGH UIC Thresholds (SECONDS)
LSCTFTT LOW and HIGH FIXED below 16MB real Storage (%)
LSCTFET LOW and HIGH FIXED/ALLOCATED Real Storage (%)
LSCTAFQ LOW and HIGH AFQ Thresholds (FRAMES)

The most common wait reason for a TSO user is "terminal-input" wait. This wait indicates the previous command has completed and the address space is waiting for the user to enter the next command on the terminal (thus terminal-waiting-for-input). The reasoning behind this is that an interactive user will spend some amount of time "thinking" between transactions. The user may "think" for one second or two hours, SRM has no way of telling how long the wait might last.

Logical swap allows a user to remain in real storage for a time interval and if the wait time exceeds this value, the address space will be converted to a physical swap thus freeing the real storage resource. The objective is to avoid swapping an address space that may shortly become active again.

NOTE: Swap-trim occurs for an address space entering logical swap status. This trimming can reduce the effectiveness of logical swap should the trimming lead to an excessive number of subsequent page-faults.

NOTE: For MVS/XA 2.1.7 users, an address space targeted for swap to expanded storage may, at the discretion of SRM, be logically swapped EVEN THOUGH LSCTMTE IS SET TO (0,0). SRM evaluates the contention for real storage and if under-utilized, will force logical swap. SRM will also reduce the degree of swap-trim for a logical swap candidate. If the logical swap becomes a physical swap, the balance of swap-trim will be performed before creation of the secondary working set.

NOTE: For MVS/XA 2.1.7 users with expanded storage - If using application packages other than ISPF under TSO, ECB wait may become the most common wait reason (rather than terminal-input). This is significant in an expanded storage environment if using the IEAOPTnn parameters that affect the destination of working-sets. ECB wait TSO address spaces are treated as part of the non-privilidged, non-terminal wait group which includes batch. Serious delays in swap-in may occur in high storage utilization situations.

Storage Isolation provides a mechanism for the system tuner to influence paging within an address space. This influence is based upon preventing page-stealing (including swap-trim) from occurring below a limit specified in PWSS as defined in the performance group definition for this address space.

Clearly, if the address space is large, preventing frame stealing from this address space could lead to more severe stealing occurring in other "non-protected" address spaces. Storage isolation does not increase the real storage capacity of a processor, it only influences the distribution of those frames among active address spaces.

Logically, if SRM/RSM are stealing pages from an address space and those pages are re-referenced soon after stealing the frames in the first place. Storage isolation is an effective tool in minimizing this type of page thrashing.

Certain address spaces (e.g. CICS, IMS, DB2, etc.) are performance critical applications and due to transaction volumes, normally cannot tolerate private area page rates above 5-10 pages per second without causing serious delays in transaction processing. These delays from suspension of the TCB in control at the time of the page-fault until the page is returned to a real storage frame. In this type of address space, protection is extended beyond the case where recently stolen pages are referenced to a point where most all pages, regardless of age, are protected. This is often necessary due to the very large working set sizes of this type of address space.

Storage isolation is a very powerful option and therefore should be used sparingly. It should only be used in specific situations where paging is causing performance degradation for an application.

Before using storage isolation, be sure there are no performance problems in the paging subsystem itself. Look for path contention, number and type of page data sets, over initiation of the system (too many active tasks), etc.

Remember, it is not necessary to stop paging altogether! The objective is to reduce paging to the point where the application will begin meeting its response time objective. The next question is: "how much storage isolation is enough?" It depends. The limits for PWSS should be high enough to do the job, but low enough to avoid impacting other address spaces. Thus the appropriate values must be determined through trial and error.

As a place to start, use a real time monitor to observe the working set size and page-fault rate for the problem region when service level objectives are being met. Repeat this observation for the region when service levels are not being met. Compare the two observations and select PWSS and PPGRT/PPGRTR parameters that appear appropriate. Implement and monitor - repeat until desired effect is obtained.

Storage isolation may also be used for swappable address spaces to alter the page stealing algorithm at the point of swap-trim. This allows the swap-out set size and thus the swap-in size to be controlled.

Storage isolation allows one to define a "working-set size" for the common area. Often, system tuners overlook the common area when implementing storage isolation. This can be a serious oversight. If the working set for CICS is protected in an effort to improve response time, but doing this places stress on the common area (common area frames are eligible for paging), we could end up with serious paging problems in the VTAM communications buffers and/or in PLPA. Page-faults in the common area can be even more impactive on response time than the original private area paging problem.

Storage isolation can be used to protect pages, it can also be used to target specific frames for stealing. If a low PWSS threshold is specified for a large batch job, for instance, those frames in the working-set that exceed the PWSS threshold are preferred for stealing. This can be a means to direct stealing to particular address spaces to free frames needed by higher priority applications.

Storage isolation can be specified as a static value or as a dynamic value. Static values are specified by PWSS and CWSS but do not take into account the paging rate. Thus the protection is fixed at the lower limit of the specification. Dynamic values allow the woking set to fluctuate in response to the private page rate within the bounds set in PWSS/CWSS.

PPGRT, PPGRTR, and CPGRT are the parameters which allow a range of paging rates to be specified. Each option allows a lower limit and an upper limit to be specified. If the private page rate is below the minimum, the working set size will be reduced - but not below the lower limit specified in PWSS/CWSS. If the private paging rate rises above the upper limit, the working set size will be increased - but not above the upper limit specified in PWSS/CWSS.

PPGRT and PPGRTR should only be specified for non-swappable address spaces. Swappable memories usually are not resident long enough for a meaningful page/sec. rate to be computed (e.g. TSO). An address space must be resident and active for 30-60 seconds before a meaningful page/sec. rate can be computed.

PPGRT and PPGRTR differ in how the page/sec. rate is computed by SRM. For PPGRT, the page/sec. rate is based upon CPU seconds or execution seconds. For PPGRTR, the page/sec. rate is based upon residency time not execution time.

For cross memory address space, always use PPGRTR rather than PPGRT. This is recommended because most cross-memory address spaces spend little time executing under their own TCB structure. Cross memory callers to this type of address space execute the instructions under the caller's TCB. There is so little execution time accumulated under the cross memory address space's TCB that it is not possible to develop a realistic page/sec. rate for use by SRM in adjusting the working-set size.

It may be becessary to use PPGRTR for a volatile CICS system rather than PPGRT if there are large variations in transaction arrival rates to CICS. The CICS region may sit "idle" for long periods and thus accumulate little execution time. In a seriously constrained real storage environment, this could result in the CICS working-set being reduced thus causing a rash of page-faults when the next burst of transaction activity arrives.

With PPGRT, the working-set will be adjusted more quickly (i.e. will adjust more rapidly to changes in execution time) than PPGRTR. If the private page-rate goes up quickly, PPGRT will cause SRM to increase protection quickly and if the rate drops quickly, SRM will decrease protection quickly.

If using PPGRTR, since the page-rate is computed over residency time rather than execution time, spurts of paging activity or rapid drops in paging activity will be averaged out over residency time and thus cause the working-set adjustment both increase and decrease to occur more slowly.

If PWSS is specified alone (PPGRT or PPGRTR not specified), SRM sets the target working-set size set to the minimum value. Page stealing may occur within the address space down to this level. Therefore, the "b" value is ignored.

If PWSS is specified together with PPGRT or PPGRTR, the working set size "floats" between low and high based upon the private page rate within the address space.

If swap-trim is reduced, the size of the working set at swap-out will increase. Reduced swap-trim also means the swap-in working set will be larger and thus take longer to physically swap back into real storage. The trade off is between spending more time swapping the working set back into real storage and spending time waiting for individual page-faults to be processed after swap-in. In most cases, it is better to suffer the slightly higher swap-in time rather than individual page-faults. The objective should be to keep trivial transaction page-fault rates below 5 per transaction (2 seems to be a good ROT number).

NOTE: For 3090 expanded storage users: Storage isolation no longer guarantees a specific resident working set (real frame working set). SRM now computes the number of real frames occupied and adds the number of expanded frames occupied to arrive at "working set size" to which the storage isolation target working set size is compared. Expanded storage frames that exceed the target working set are eligible for migration to auxiliary storage should expanded storage become constrained. Since we can no longer control resident set size, it seems we are to believe that page-faults from expanded storage are of no concern since they only take 70-75 micro-seconds compared to 15-20 milli-seconds for auxiliary storage.

Before using storage isolation, be sure there are no performance problems in the paging subsystem itself. Look for path contention, number and type of page data sets, over initiation of the system (too many active tasks), etc.

EXPANDED STORAGE MANAGEMENT

Expanded storage is managed by RSM under control of SRM. Pages move from real to expanded storage under control of RSM but only after checking with SRM to see if it is OK. Pages move from expanded storage to real storage under control of RSM. The page-fault interrupt handler receives control after the PIC 11 and gives control to RSM who determines the location of the page (could be in expanded storage or on auxiliary storage). If in expanded, a synchronous page move is done to physically move the page from expanded to real. Clearly, this process consumes CPU cycles. The time required to resolve a page-fault from expanded storage is estimated by IBM to be 75 micro-seconds for standard 3090 models and 70 micro-seconds for 3090-E models. Of this time, approximately 30 micro-seconds is spent actually moving data. The other 45 micro-seconds are spent in the interrupt handler and RSM code.

Swapping is also performed (under SRM control) to expanded storage and again, RSM must perform the page movement operations required to move the working set into expanded storage. Note that there is no "block-paging" capability for expanded storage. Each page in a swap operation is moved individually. There is a cross over point where the CPU overhead to swap an address space from auxiliary storage is less than that for a similar swap from expanded storage.

As with any hardware/software feature release, we must look at what expanded storage offers, but also how it affects the existing knowledge base for tuning procedures and capacity planning.

A group of new IEAOPT parameters has been added to provide some input about how we would like SRM to manage expanded storage frames. These OPT parameters work in conjunction with the Criteria Age Table and Migration Age.

The criteria age table allows SRM to regulate direct use of expanded storage through determining what type of pages are sent into expanded storage. The criteria age table values are changed through use of the IEAOPT expanded storage parameters. These parameters allow decisions to be made about where a particular address space should be swapped: to expanded storage or directly to auxiliary storage?

Unfortunately, these parameters only affect swapping decisions if expanded storage becomes constrained (i.e. migration age drops below 32,767). Therefore, you cannot absolutely determine the swap destination for a particular type of address space.

Migration is the process used by RSM and SRM to manage expanded storage frames. The primary purpose is to maintain a supply of available expanded frames for use by RSM for page-outs and swap-outs. Migration describes the process of determining how long a page remains in expanded storage and thus determins when old "inactive" pages are to be sent to auxiliary page data sets. Migration is not controlled by IEAOPT parameters. It is dynamically controlled by SRM and is adjusted based upon demand for expanded frames.

NOTE: The channel subsystem cannot access expanded storage, so migrating pages must be moved back into REAL memory before ASM can page them out to auxiliary.

Some old tuning terms have changed meaning with the addition of expanded storage. Working set now represents the total of frames occupied in real storage and the frames occupied in expanded storage. This dramatically changes how storage isolation functions. Storage isolation no longer holds frames in real storage.

A Page fault is not counted if resolved from expanded storage. It is only counted if a reclaim or physical I/O to auxiliary storage was required. This affects all the OPT parameters that trigger on demand page rate or page-fault rate.

Migration age is supposed to give you some idea about how long a typical page will remain in expanded storage before migrating to auxiliary. The stated purpose of migration age is to function in a manner similar to UIC for real storage management, but unlike the page frame table which contains a counter for UIC, there is no equivalent counter for an individual expanded storage frame.

There are three types of migration that can occur in expanded storage systems. First is LRU migration. LRU migration is triggered by a shortage of available expanded storage frames. Second is Re-configuration migration which is used to move pages out of expanded storage frames which are being varied off-line. The third type of migration is Purge migration. This is the process of moving the secondary and/or primary working set of an address space from expanded frames to auxiliary storage. Neither re-configuration nor purge migration alters the migration age. Therefore, you may see migration occurring from expanded to auxiliary storage while a very high migration age exists.

For an address space that is actively executing in real storage, the working set will consist of a residence set which is the current number of real frames occupied. All other pages that belong to this address space will be either in expanded storage or on auxiliary storage and are considered to be "non-working set pages".

For an address space that is to be swapped to expanded storage, the residence set (those frames surviving swap-trim) will be divided into two parts: primary working set and secondary working set. This division is performed by RSM as part of the swap process, but is only performed for swaps to expanded storage. Direct swaps to auxiliary storage are performed without division. The primary and secondary working sets are then moved into expanded storage if SRM approves (i.e. if there are enough expanded frames available to contain the swap pages).

The address space now has three distinct parts: primary working set, secondary working set, and non-working set pages.

The primary working set consists of: LSQA, Fixed frames, and a single frame for each segment used by the address space. The secondary working set consists of: All working set pages not in the primary working set including storage isolated frames. Non-working set pages are what ever is left over.

Swap migration is a multi-step process. If, during LRU migration processing, RSM finds that the next page to be migrated from expanded storage frame is part of the primary or secondary working set for an address space (a bit in expanded storage table entry indicates this fact). RSM then asks SRM for a special type of swap (migration swap) which will be used to send the remaining portions of this address space to auxiliary. First, the secondary working set pages will be sent to a local page data set. Then the primary working set will be sent to a swap data set (if there is one) or to local page data set.

When the address space becomes active again, it must now be swapped in from auxiliary storage using a two-stage swap-in process. The primary working set comes in first. The address space is now dispatchable. Secondary working set pages revert to "non-working set" status and are retrieved through page-fault processing (shades of pre SP 1.3).

The implementation of expanded storage required some additional selection criteria be developed to help determine what type of address space should be sent to expanded storage and what type to send directly to auxiliary. There are three classes of users: Non-swappable/Common area/Privileged, TSO Sessions in Terminal Wait, and all others (other TSO, batch, etc.).

These classifications allow distinctions to be made about how to handle types of page operations based upon resource contention. Thus when real and expanded storage become constrained, "non-critical" address spaces may be sent directly to auxiliary and bypass expanded altogether.

For each class of address space, there are also classes of pages. This provides a mechanism for tuning expanded storage based upon type of page request and type of address space.

- SWAP Trim, changed pages
- SWAP Trim, unchanged pages
- SWAP Working Set (TSO terminal input)
  primary/secondary working set
- PAGE-OUT, unchanged pages demand page-outs
- PAGE-OUT, changed pages
- STEAL, changed pages page steals
- STEAL, unchanged pages
- Virtual fetch paged virtual fetch

AUXILIARY STORAGE MANAGEMENT

Auxiliary storage is still with us - even with expanded storage. The old rules of thumb still apply when it comes to paging subsystem design. The number of page data sets required is based upon the volume of page

movement to auxiliary. The number of volumes must then be spread over the I/O subsystem in such a way as to provide parallelism through channel paths and devices.

Additional configuration choices include the type and combination of page data sets - whether to swap to local page data sets or include swap data sets and use of directed VIO to separate VIO paging from demand/swap paging.

The introduction of the seldom ending channel program in MVS/SP 1.3 was an interesting approach to reducing the Start I/O overhead for ASM channel programs. Suspend/Resume provided the ability to "suspend" a channel program and resume it at a later time using a fast-path line through IOS. This worked well, except that the suspend status was stored in the sub-channel for the page device. This means that as far as IOS is concerned, the device is still busy.

If another non-ASM I/O request is made to the volume, IOS informs ASM that someone else wants to do I/O to the device and ASM must terminate the suspended channel program. IOS may them allow the non-paging I/O to begin on the device. This situation should be avoided - especially in moderate to heavy paging situations where this handshaking can be very expensive to paging operations.

In addition, if you are running MVS/XA, you must consider interrupt subclasses. There are now two categories of I/O interrupts. The first is paging, the second is non-paging. Paging interrupt subclass is associated with the UCB containing a page data set. However, since the association is through the UCB and not the data set, all I/O interrupts occurring on this device will receive the paging interrupt subclass (even if for a non-page data set).

Avoid allocating non-page data sets on page volumes - and if you do, don't access them during peak paging periods. Specifically, avoid placing INFO/MVS, SMP DLIBs, etc. on the back end of a page volume.

SUMMARY

- Paging is a design feature of virtual storage
- Don't expect SRM to fix severely over-committed memory
- Memory management should follow dispatching priorities
- Avoid using absolute controls
- Utilize dynamic memory controls
- Logical swap - last use for "extra" memory
  (extend use for expanded storage)
- Use storage isolation carefully - diminishing return
- Don't use Storage Isolation to compensate for other problems in paging subsystem

ABSTRACT

The System Resources Manager (SRM) component of the IBM MVS operating system controls the allocation of resources to the various users of the system. In this paper the memory control algorithms of the SRM are studied, and a model is proposed. The model distinguishes between different operating conditions of the system, reflecting the behavior of SRM control as the memory demand increases. Results are presented for a single class time sharing model. Some suggestions are given for measurement procedures, and for a multiple class model. The difficulties in collecting the model and workload parameters precluded model validation. In its current form, the model can be used to gain a better understanding of the SRM memory control algorithms.

1. Introduction

Modeling memory constrained systems is difficult, since not only the CPU and (non-page/swap) I/O load must be quantified, but also the paging and swapping load. The paging and swapping load depends not only on the characteristics of a transaction or job, but also on the system load: as contention for memory increases, the paging load will increase as well. On the top of that, the operating system will adapt its behavior to the memory contention it observes.

In this paper we will describe a model that includes memory contention as indicated by both paging and swapping. Although the model was primarily designed to match the memory control algorithm of SRM in an IBM MVS system, a similar methodology can be applied to other systems.

Section 2 of this paper describes the operation of the SRM's memory control algorithms and introduces the terminology used in this paper. Section 3 describes a model for these algorithms. In section 4 results are presented for a single class model. Section 5 discusses extensions to a multi-class model. Some measurement and validation procedures are evaluated in section 6. Finally, section 7 summarizes the results.

2. SRM Memory Control

In a large time sharing system many terminal users and batch jobs have to compete for the system's resources. In an IBM MVS system, it is the responsibility of the System Resources Manager (SRM) to allocate the resources in the system to its users, in such a way that the throughput is maximized and/or that each user receives the service he is entitled to. The resources controlled by SRM include the processor, the I/O devices and channels, and main memory. In this paper we will focus our attention to the main memory control algorithms. In most of the discussions in this paper, it is assumed that no I/O or CPU bottlenecks exist.

The MVS unit of memory allocation is a page. For each active task, only a certain number of pages are allowed to be in main memory. The pages kept in main memory are those that were referenced most recently, since they are most likely to be referenced again. In this paper the term *working set* will be used to refer to the pages in main memory for a task; the size of this operational working set thus depends on the system load [cf Denning 1980]. SRM adjusts the working set size for each task in main memory, based on the *Unreferenced Interval Count* for the individual pages.

A UIC is maintained for each page in main memory (frame in MVS terminology) indicating how long it has been since a task referenced it [IBM 1985]. Each second, SRM will increment the UIC counter for each frame that has not been referenced during the last second[1]. If it is necessary to make room for more tasks, SRM removes from all active tasks those pages that have their UIC equal to the highest UIC in the system, until sufficient room is available. This guarantees that the age of the oldest unreferenced page is approximately the same for all tasks in the system [IBM 1982].

In an unconstrained system, the UIC for each task will be high, since there is no need to remove old pages before termination of the task. As the load goes up, it will more frequently be necessary to remove the oldest pages (with the highest UIC). This results in smaller working sets, making room for more tasks, but also increases the probability that a page referenced is not in main memory. Such an event is called a page-fault; the task will continue its execution as soon as the page is loaded into memory again.

In a time sharing environment the users spend most of their time thinking and typing. They only consume system resources when their transaction is active. If sufficient memory is available to hold the pages for both the thinking and the active users, there is no need to load these pages into main memory for each transaction (swap-in), and to remove them each time a transaction is completed (swap-out). Instead, SRM performs a *logical swap*: the user is deactivated but kept in memory when a transaction completes. If sufficient memory is unavailable, a *physical swap* is performed for (some of) the users: the user pages are written to external memory when a transaction completes.

1. In MVS/XA this is not strictly true, as the update of the UIC is less frequently done if the memory utilization is low.

* Although the author is currently employed by IBM, the opinions expressed together with the recommendations made are strictly his

SRM bases this *swap decision*, i.e. whether to perform a logical or physical swap, on the *system thinktime* and the observed user thinktime from the transaction just completed. If the user thinktime exceeds the system thinktime, a physical swap is done. If not, a logical swap occurs. The idea is that users with a short thinktime will have their next transaction ready soon, so it is beneficial to keep them in memory. Essentially, the memory allocated to logical swapping is used as a cache for the most active tasks. The system thinktime is derived from the UIC: every 20 seconds the SRM will increase the system thinktime by 0.5 second if the UIC exceeds 30, decrease it by 1 if the UIC is less then 20, and keep it unchanged if the UIC is in the range 20..30[2]. The result is that the system thinktime (and thus the swap probability) is adapted such that the UIC is kept in the range 20..30. It will be clear that no control is possible as the system thinktime reaches zero, i.e. if all users are physically swapped for each transaction.

If SRM is unable to make room for more tasks by lowering the system thinktime because all users are physically swapped for each transaction, the UIC will further drop, until either the CPU is saturated, the paging rate becomes too high, or the UIC reaches 2[3]. When either limit is reached, pages are no longer stolen from active tasks, but entire tasks are removed from the main memory instead. Removing tasks will reduce the memory constraints and allow the UIC to go up. This process is called *exchange swapping*, since active tasks are swapped in and out memory. SRM controls the swap mechanism in such a way that each task receives its share of the total system capacity, in accordance with the SRM control parameters.

More swap mechanisms do exist, but they are not relevant to this discussion.

Figure 1 shows the memory layout for an MVS system under increasing load conditions, and the swapping that takes place in each case. Five different situations are discerned, in order of increasing memory contention. The figure shows the use of main memory for each situation, differentiating between *active users* (executing a transaction) and *logically swapped users* (in the think time). For clarity of presentation a single user class is assumed, consisting of terminal users.

Situation A in Figure 1 describes an unconstrained system: all user programs fit into memory easily. The UIC will be 255 (the maximum value), almost no paging occurs and no physical swapping takes place. Characteristic for this situation is that the memory is large enough to hold all tasks at their maximum working set size. The working set size in this system is defined as WS_{max}, since no page stealing takes place.

Situation B in Figure 1 describes a lightly loaded system, where some paging occurs since the working set is reduced to make all users fit in memory. No physical swapping occurs, since the UIC is still greater than 30.

Situation C in Figure 1 describes the normal load range where logical swapping is gradually replaced by physical swapping, based on the user and system thinktime. The UIC will vary between 20 and 30 in this area, since the system thinktime is used to control the swap decision, as described above. The working set size remains approximately constant in this situation, since the UIC is kept constant. The working set size for this area is referred to as WS_{normal}.
As more users are added to the system, the physical swap probability will increase to 100%.

Situation D in Figure 1 describes a heavily loaded system, where all transactions are physically swapped; the swap probability is 100%. Under these load conditions SRM will further reduce the working set, until the UIC reaches 2, the CPU is saturated[4], or the paging rate

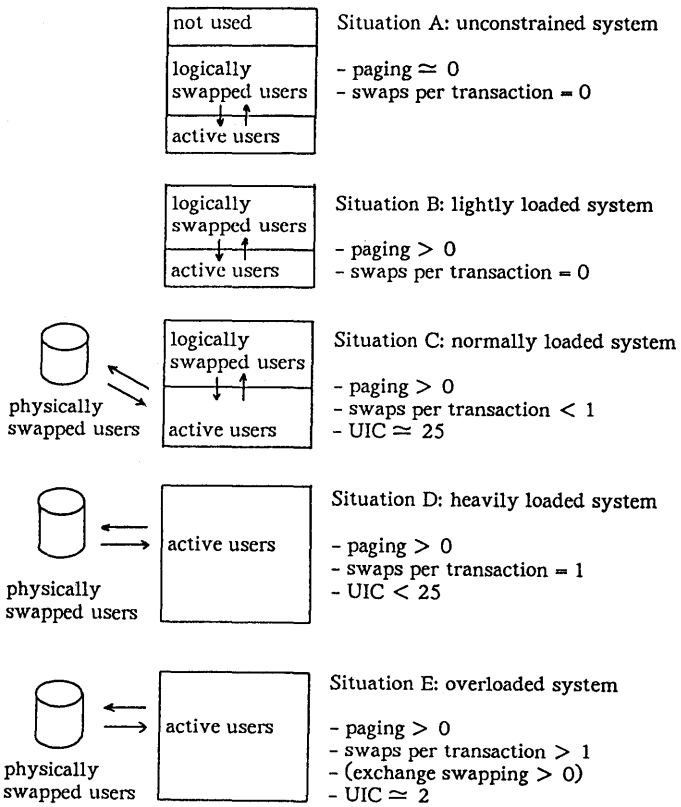

Figure 1. Memory layout for various system load conditions

becomes excessive[5]. The working set size corresponding to a UIC of 2 is defined as the WS_{min}, since SRM will no longer attempt to reduce it.

Situation E in Figure 1 describes the overloaded system condition: not all active tasks fit into the available memory, even if their working set is reduced to the bare minimum. SRM copes with the situation by starting exchange swapping: tasks are permitted to accumulate some service while in main memory, but are exchanged if their gain as compared to a swapped-out task exceeds some threshold. The active users are now partially kept in memory and partially waiting to be swapped in with an exchange swap. As more users are added to the system, the number of swapped out users will increase, without any increase in throughput.

2. 20 and 30 are the default thresholds; they can be changed using PARMLIB controls.
3. The definition of CPU saturation, high paging rates and low UIC can be changed using PARMLIB controls.
4. At least one task was waiting for CPU service during an entire SRM second.
5. The number of page faults per second is above a CPU dependent maximum value.

The values for some performance values and control parameters in the system under the situations described are sketched in Figure 2. The figure shows each parameter as a function of the system load. The UIC (shown in top) is the key control parameter for SRM; it is more or less constant in the unconstrained (A), normal (C) and overloaded (E) system conditions. The working set size is also constant in these situations, as shown with the second line. In the unconstrained situation (A) the UIC is constant at its maximum value. In the normal load situation (C) SRM controls the system throughput with the physical swap probability; the number of swap(-ins) per transaction rises from 0 to 1. In overload situation (E) exchange swapping is used in an attempt to reduce the memory constraints; the number of swaps per transaction now exceeds 1.

The system-wide paging rate will increase throughout A-D, since more users become active in memory (shown with the fourth line). Note that the system paging load in normal load situation (C) increases because more users are added to the system; the paging load for individual transactions remains constant, because the working set size remains the same.

In the overload situation (E) both the working set size and the number of swapped-in users remain constant as the load increases. The system throughput will decrease, since more time is required for the exchange swaps, as more users have to be served.

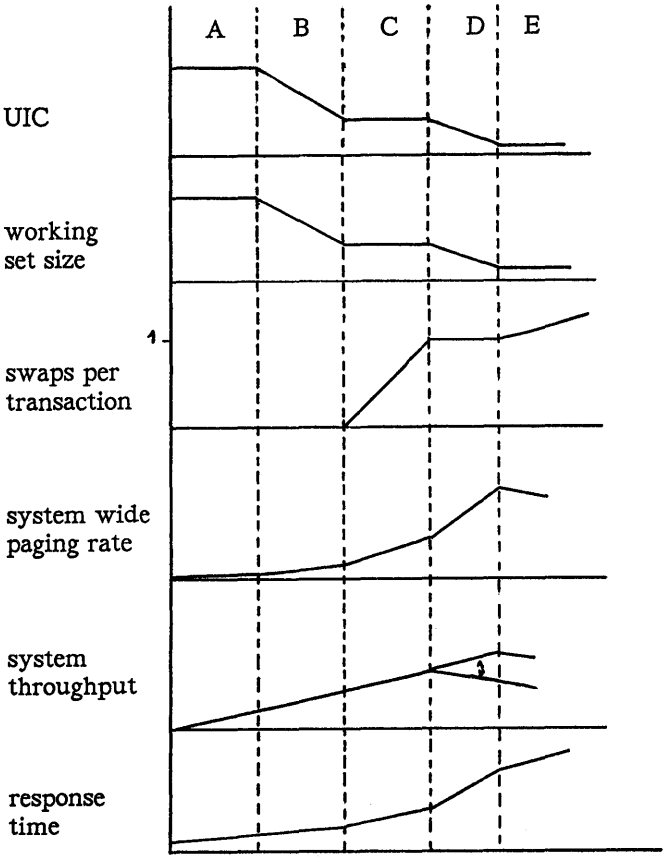

Figure 2. Performance and control parameters as a function of the memory contention (not to scale).

3. SRM Model

Each of the situations described above corresponds to a different behavior of the SRM control algorithms. The model described in this section reflects this: each situation is modeled separately.

Standard queueing models describe the workload of a transaction in terms of the CPU load and the I/O load to the various devices. For any model that should predict the paging and swapping load under varying load conditions these parameters are unsufficient: some information on the working set sizes and the corresponding page fault probabilities must be available.

In the model described it is assumed that for a given working set size, the probability that a page fault occurs can be computed (or is available from measurements), that is

$$P_{pagefault} = f\,(WS)$$

Furthermore, it is assumed that the working set size is a function of the UIC only, that is

$$WS = g\,(UIC)$$

The notion is that the UIC is a measure of memory contention in the system; for a given value of the contention index (the UIC), the working set size will be constant. This assumption is not strictly true, since the UIC counters are incremented each SRM second for all pages that have not been referenced during the last SRM second. That is, when only one task is active, it can execute about 1 million instructions during the SRM second. If n tasks are active, each task can execute only $1/n$ million instructions, and will reference less pages in its working set. The result is that in a heavily loaded system the UIC will be higher for a given working set size. In the model presented this effect is neglected. At first sight, this seems to be a problem with the model. You should realize, however, that any measurements performed in a real system will automatically account for this effect: a low UIC occurs when the load is high.

With these assumptions both the working set size and the number of page faults for a transaction can be computed from the UIC. One can also say that the relation between the working set and the page fault probability is known, and that the UIC tells at which point of the curve the system operates.

Looking at it this way, it is easy to see that other memory control policies can be described with a similar model, as long as the operating system maintains some kind of "memory contention indicator". For example, in a UNIX system one could use the page scan rate as a measure of contention [van Someren 1984]. In a VM system, the core table scan rate could be used [Beretvas 1986].

In the SRM model described below, the relations between the UIC, working set size and paging rate are used to compute the number of page faults per transaction, as a function of the number of terminal users. The model consists of a high level SRM part, which mimics the SRM control algorithms, and a low level submodel that provides response times and throughputs once the page and swap load are known.

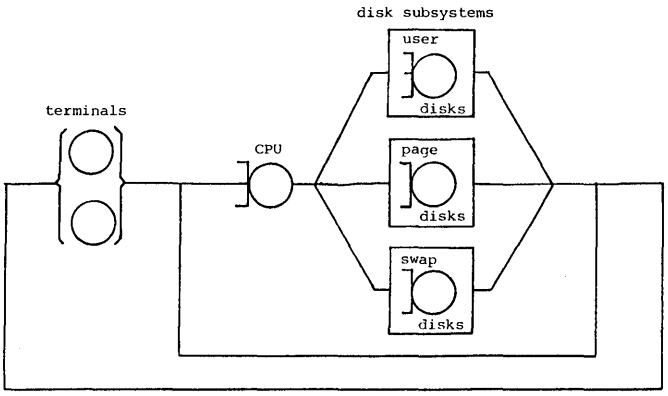

Figure 3. System submodel used

The system model used as a low level submodel is shown in Figure 3. It consists of a (variable) number of terminals, a CPU, and user, paging and swapping disks. The system model is solved using the Mean Value Analysis (MVA) method. For the disk drives, contention at the controller and channel level is modelled with a separate model, using the method proposed in [Lazowska, 1985]. This disk model computes the disk service time for a known throughput, initially estimated to be zero. The standard MVA method is then used with this service time estimate to compute a new throughput, to be used for a new disk service time estimate. The process is repeated until the throughput is sufficiently accurate.

For the purpose of this paper, the system model can be considered to be a black box, which accepts the number of terminals and the service demands for CPU (D_{CPU}), user I/O (D_{user}), paging (D_{page}), and swapping (D_{swap}) as parameters, and provides the system throughput and response time for these load conditions.

The algorithms used in the high level SRM model to compute the service demands for the low level model, are described in detail in the next subsections, for each of the situations A-E separately.

Basically, it is assumed that the SRM adjusts the UIC in situation B and D, the physical swap probability in situation C, and the exchange swap probability in situation E such that the tasks fill up the entire memory.

This is accomplished by setting the service demands for the system submodel, evaluating the submodel, and using the submodel results (particularly the overall response time and throughput) to obtain new estimates for the service demands.

The description below will be based on a single class model, with a time sharing workload (TSO).
The following notation is used:

$N_{terminal}$ the total number of users (active and thinking)

D_{CPU} the CPU service demand per transaction, including the overhead for paging and swapping

D_{user} the user I/O service demand per transaction for the non-page, non-swap disks

D_{page} the service demand per transaction for the paging disks

P_{page} the page fault "probability", expressed in the number of page faults per 1 million instructions

D_{swap} the swap demand per transaction for the swapping disks

P_{swap} the numer bo swap-ins per transaction

N_{active} the number of active users

$N_{outready}$ the number of users swapped out by exchange swapping

$WS_{\min}$ the working set size corresponding to the minimum UIC (2)

WS_{normal} the working set size corresponding to the UIC in the normal load situation (C)

$WS_{\max}$ the working set size for an unconstrained system (UIC large)

MemorySize the amount of main memory available to hold user tasks

3.1 Unconstrained System (situation A)

In situation A sufficient memory is available to hold all active and thinking processes. Since all tasks fit entirely in memory, the working set for each task is equal to $WS_{\max}$. The maximum number of users N_A accommodated in situation A is found as

$$0 \leqslant N_A \leqslant MemorySize / WS_{\max}$$

If the number of terminals $N_{terminal}$ is in this range, the working set size per task is known in advance: it is at its maximum value. The page fault probability follows directly from $P_{pagefault} = f(WS_{\max})$. The service demand for the paging disks per transaction can now be computed as

$$D_{page} = P_{pagefault} D_{CPU} = f(WS_{\max}) D_{CPU}$$

No swapping will occur in this unconstrained situation, so $D_{swap} = 0$. Since both D_{page} and D_{swap} are independent of the system response time and throughput; a single evaluation of the system submodel is sufficient.

3.2 Lightly Loaded System (situation B)

In situation B sufficient memory is available to hold all tasks, be it at a reduced working set size. SRM will steal pages from the active tasks, until all tasks fit into memory. The working set size reduction corresponds to a UIC reduction from the maximum UIC (255) to the "normal UIC", that is the UIC value in situation C (approximately 25). The system is in situation B if the number of users N_B is in the range

$$MemorySize / WS_{\max} < N_B < MemorySize / WS_{normal}$$

The working set size for a specific number of users $N_{terminal}$ is computed as

$$WS = MemorySize / N_{terminal}$$

From this working set size the page fault probability and the UIC (from the inverse of $WS = g(UIC)$, thus $UIC = g^{-1}(WS)$) can be computed. Note that the function g is a strictly increasing function for situation B, so the inverse function will exist. Like for the unconstrained system, no swapping occurs. Also, only a single evaluation of the system submodel is required since D_{page} and D_{swap} are again independent of the submodel results.

3.3 *Normally loaded system (situation C)*

In situation C sufficient memory is available to hold all *active* tasks. The working set size for each task is WS_{normal} since the UIC is approximately 25 over the entire interval. Since the UIC is constant, the number of page faults per transaction is also constant in this situation ($P_{page} = f(WS) = f(g(UIC))$). Since the number of transactions handled per second will increase as the number of users increases, the system paging rate will increase.

SRM controls the usage of memory through the physical swap probability; as more users are logged on, the probability for a physical swap will increase.

The system is in situation C if the number of terminals N_C exceeds $MemorySize/WS_{normal}$ and all active tasks fit in the memory, that is $N_{C,active}$ must not be larger than $MemorySize/WS_{normal}$.

In solving the model the physical swap probability P_{swap} is initially assumed to be one, i.e. all users are swapped ($P_{swap} = 1$). From the P_{page} and P_{swap} a first estimate for the service demands for paging and swapping can be computed. With these demands, the system submodel is used to estimate the number of active users N_{active} in the system. Multiplying N_{active} by the working set size WS_{normal} yields the memory used for active tasks. When the active tasks do not all fit into memory ($WS_{normal} N_{active} > MemorySize$), it is assumed that the system is in situation D or E. When they do fit, the remaining memory is used to hold $N_{LogSwap}$ logically swapped users, with

$$N_{LogSwap} = \frac{MemorySize}{WS_{normal}} - N_{active}$$

Once the number of logically swapped users is known, a new estimate of swap probability can be obtained. As a first approximation, it is assumed that the logical swap probability is proportional with the number of logically swapped users. The physical swap probability then equals [Lazowska 1984]

$$P_{swap} = 1 - \frac{MemorySize/WS_{normal} - N_{active}}{N_{terminal} - N_{active}}$$

The numerator gives the number of logically swapped users, the denominator gives the number of users not currently active. In a real system, the swap probability would probably be less than the value estimated here, since the most active users tend to remain in memory (SRM based its swap decision on the previous think time). These users also generate the largest part of the load.

The P_{swap} found from the equation above is then used to improve upon the first estimate for the swap service demand, which set the probability P_{swap} to 1. The model is solved again for the new P_{swap}, and a new N_{active} results. The process is repeated until P_{swap} is constant.

3.4 *Heavily loaded system (situation D)*

In situation D all active users are kept in memory, but their working set must be reduced below WS_{normal}. SRM cannot control the memory utilization through the logical swap mechanism, since all users are swapped for each transaction. Instead, SRM will initiate page stealing, thus reducing the average working set for the active tasks, and making room for more tasks.
The system is in situation D if

$$MemorySize/WS_{normal} < N_{D,active} < MemorySize/WS_{min}$$

Since the number of active users $N_{D,active}$ is proportional to both the response time and the throughput (Little's Law), a reduction of the working set size from WS_{normal} to WS_{min} may not have the desired effect of making room for more users: the reduced working set results in higher paging rates (D_{page} increases), increased response times and ultimately in an increased time-space product (a large page-seconds value in the MVS terminology).

In solving the model, the working set size is reduced in a few steps. At each step, the paging demand is computed using $P_{pagefault} = f(WS)$. The system submodel is used to compute the number of users $N_{D,active}$ in the system. If it is in the proper range, a better estimate is obtained through iteration. If no $N_{D,active}$ can be found for any UIC, the system is in situation E.

3.5 *Overloaded system (situation E)*

In situation E the memory cannot hold all active users; exchange swapping is used by SRM to limit the number of swapped in users. Since the UIC is kept constant at its minimum value, the number of page faults per transaction will be constant (but high). The page fault probability equals $P_{pagefault} = f(g(UIC_{min}))$. Each task in memory is kept at WS_{min}; the number of swapped in users equals

$$N_{swappedin} = MemorySize/WS_{min}$$

In the model for exchange swapping both the I/O overhead for each exchange swap and the wait time while swapped out must be included.

We first solve a system submodel with $N_{swappedin}$ customers, assuming a single swap in and swap out for each transaction. This submodel yields the maximum throughput the system can handle, at the given swap probability. Note that this submodel differs from the submodel discussed previously in that no terminals are included. Instead, the throughput from the submodel without terminals is used in a two server model (system and terminals) to determine the average number of waiting users. The waiting users in the model are equivalent to swapped-out users; they are "out ready" in terms of the SRM.

The number of swaps per transaction is now approximately

$$P_{swap} = 1 + \frac{2N_{outready}}{N_{active}} \cdot \frac{CPUload}{ISV}$$

and

$$N_{outready} = N_{active} - N_{swappedin}$$

with

CPUload the average service demand for a transaction

ISV the CPU service provided to a customer in a single swapped in interval.

The term "1" in the equation says that each job is swapped in when the transaction starts. The factor $CPUload/ISV$ says that a job is exchange swapped after it used *ISV* service[6] from the processor.

6. The ISV parameter corresponds to the SRM ISV parameter on the performance group command in the IEAIPS PARMLIB member.

The factor $N_{outready}/N_{active}$ says that the number of swaps is proportional with the fraction of users swapped out. The factor 2 says that an exchange swap involves the movement of two jobs. Note that the N_{active} includes both the "in ready" ($N_{swappedin}$) and the "out ready" users.

After the first evaluation of the system submodel a new estimate for the number of swaps per transaction can be obtained, and the submodel can be evaluated again using a more accurate swap I/O load. The process is repeated until the swap probability is essentially constant.

4. Model results and discussion

To use the model we need to make estimates for quite a few system parameters. The system modeled consists of a processor, eight user 3380 disks, eight paging disks (3380 or solid state), and sixteen 3380 swapping disks. As described before, channel and controller contention are modeled in the I/O subsystem. A single time sharing workload is assumed, with a varying number of terminals.

The load and system parameters used are specified in Table 1, in terms of instructions (for the processor) and I/O requests (for the disks).

TABLE 1. Workload and system description.

workload:		
CPU load	500.000	instructions
I/O load	5	I/O
system:		
processor speed	18	MIPS
page fault CPU overhead	10000	instructions
page fault I/O load	1	I/O
swap CPU overhead	25000	instructions
swap I/O load	3	I/O
pages per swap	12	pages
Memory Size	32 or 64	MByte

Furthermore the working set and paging characteristics used are given in Figure 4 as a function of the UIC. The working set size is expressed in Kbytes, the page fault probability in the number of page faults per 1 million instructions.

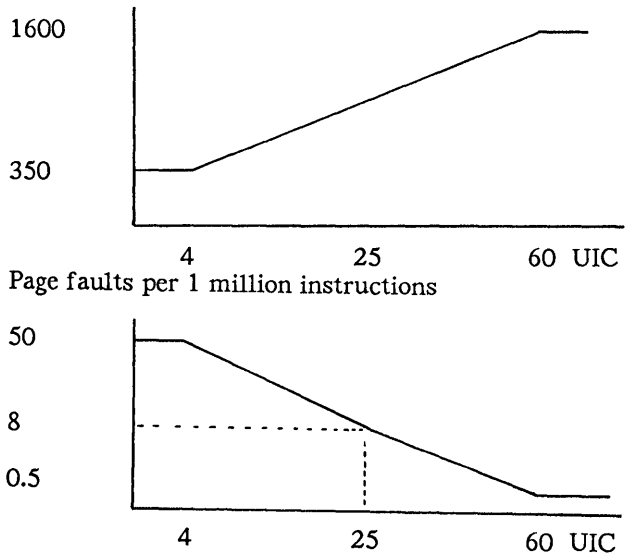

Figure 4. Working set size and number of page faults per 1 million instructions as a function of the UIC.

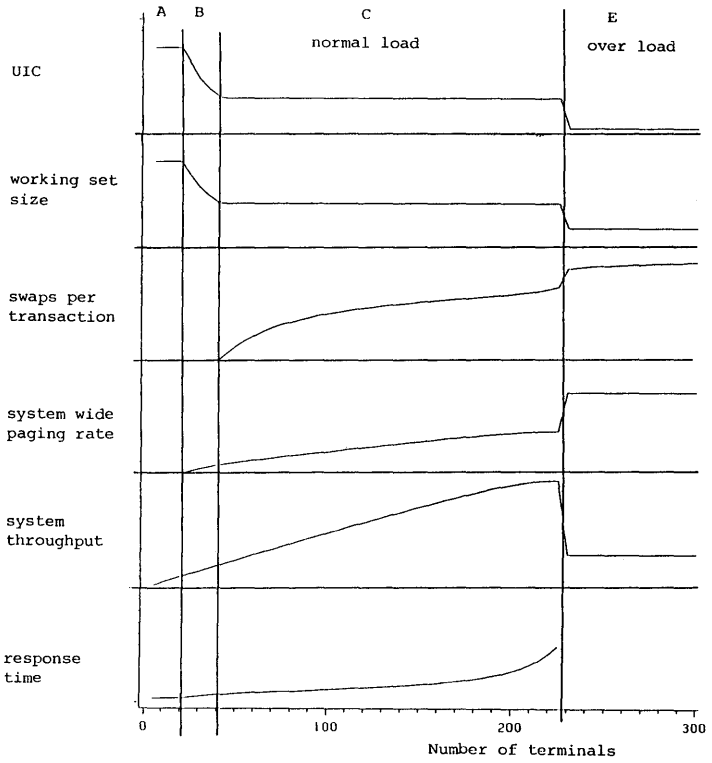

Figure 5. Model results for a system with 32 Mbyte memory and 3380 paging disks.

Figure 5 shows the modeling results for a system with 32 Mbyte of real memory, using standard 3380 disks. The system configuration and workload are dimensioned to create a CPU and/or paging bottleneck; ample capacity is provided for swapping and user I/O.

The system shows a reasonable behavior in the situations A to C, but it obviously cannot handle the paging load in the overloaded system situation (E): the throughput suddenly drops. In the normal load situation C the paging demand is constant for individual transactions, but the system wide paging rate increases significantly, proportional with the system throughput. The number of swaps per transaction increases from 0 to 1 in situation C. It is interesting to note that the heavy load situation (D) does not show up in these results: apparently the working set reduction was offset by the large increase in paging. The sudden collapse in performance in this system is due to a paging bottleneck.

In a real MVS system under SRM control this would not happen if the CPU utilization or paging rate exceeded one of the thresholds, explained before.

The response time has also been evaluated for three other configurations, with upgraded main memory (64 instead of 32 Mbyte) and/or faster paging I/O (solid state disks instead of 3380). The results are shown in Figure 6. The systems shown are

1. 32 MByte main memory, 3380 paging disks,
2. 32 MByte main memory, solid state paging disks,
3. 64 MByte main memory, 3380 paging disks,
4. 64 MByte main memory, solid state paging disks.

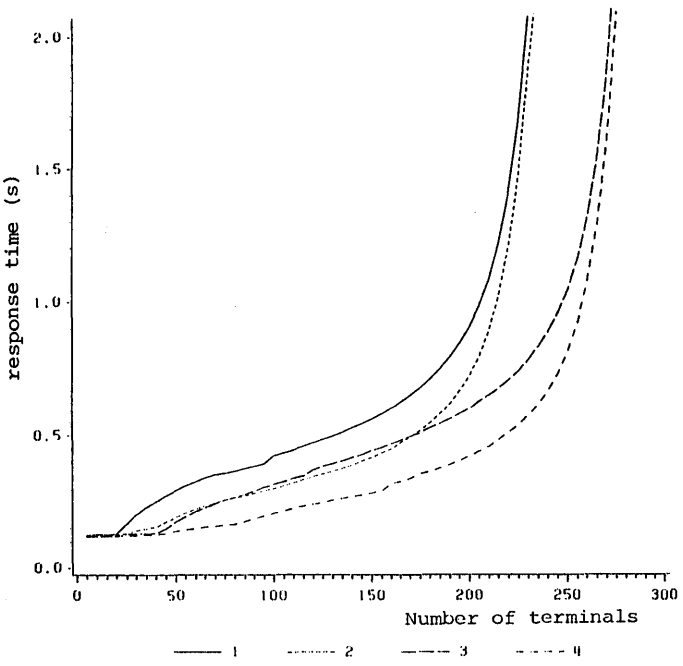

Figure 6. Model results for four different memory and paging configurations.

Obviously, the system with the smallest main memory and the slowest paging disks performed worst. It is interesting to compare the systems 2 and 3: the system with the fast paging disks (2) performs similar to the system with a large memory (3) for up to 200 terminals. In terms of a large MVS system this means that a fast paging device (solid state disk or cached paging controller), which provides very fast access to page datasets, can be a viable alternative for a memory upgrade. At higher loads (more than 200 terminals), the memory constraint really shows up. At high paging loads the CPU overhead and channel bandwidth limit the system performance; a fast paging device no longer provides a performance advantage. Therefore, the response time for the DASD and solid state systems converge.

Of course, all results depend very much on the assumed relation between UIC, working set size, page fault probability and configuration.

5. Model extensions

The modeling approach is based on the fixed relationships between the UIC, working set size and the page fault probability. For a multi-class model the same reasoning can be applied: the working set size and the page fault probability can be computed for each class independently from the UIC, which is of course the same for all classes.

Equations that involve the working set size must now be written as vectors, e.g. the system is in the lightly loaded situation B if and only if

$$\sum_t N_{t,t} WS_{max,t} > MemorySize > \sum_t N_{t,t} WS_{normal,t}$$

Similar reasoning applies to the other situations, although the formulas for the normal and overload situations are somewhat more complex. In these situations it is crucial to define how the classes compete with each other: should they receive the same treatment (i.e., the same swap probability) or should preference be given to a certain class. Basically, both assumptions can be handled with appropriate formulas.

The two level modelling approach, with a high level model describing the SRM algorithms and a low level model describing the system's hardware can also be applied to model other facets of SRM behaviour. For example, the MPL controls which are based on the system wide paging rate and CPU utilization could be included in the model. Also, a more detailed model could be used for paging and swapping reflecting some of the control mechanisms used by the Auxiliary Storage Manager (ASM).

Such extensions are feasable, since the two level model can use the same feedback control as the operating system components.

6. Measurement and validation procedures

Until now no reference was made to any measurement data. Still, for the model to be useful it is crucial that the relationships between the UIC, working set size and page fault probability are known.

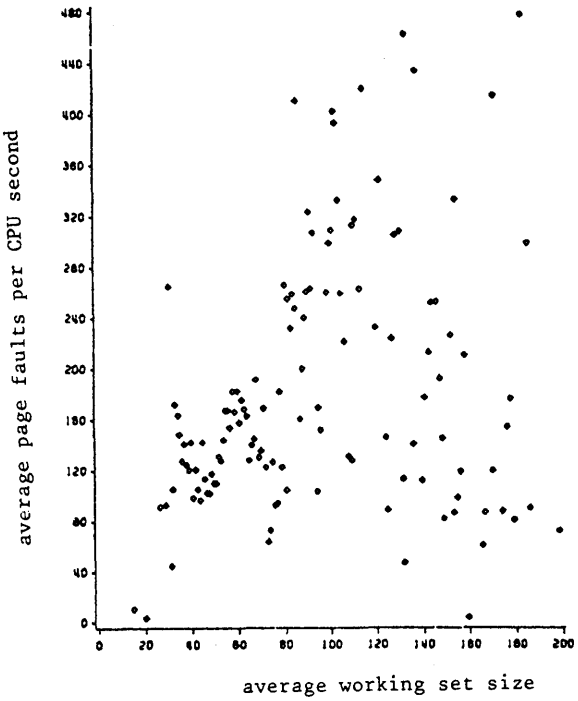

Figure 7. Average number of page faults per (3083) CPU second used, as a function of the average working set size for TSO ISPF users.

In the IBM MVS system, logging data is available on the average working set size, the number of page faults and the CPU time used for each completed task. This data seems particularly useful for obtaining the relation between the average working set size and the paging rate for a given workload. Unfortunately, this does not work very well in practice: in a "real" system the workload tends to be too heterogeneous, i.e. the number of

page faults per CPU second plotted against the average working set size tends to show little correlation.

Figure 7 shows the average number of page faults per CPU second as a function of the average working set size for all TSO-ISPF users in the system. Each point represents the average for a specific number of pages. This plot does not show a reduction in the number of page faults as the working set increases. Instead, it seems to tell that larger programs generate more page faults. The problem with such measurements is that the individual observations represent different users, running different programs. This makes it very difficult to obtain useful model parameters.

Figure 8. Average number of page faults per (3083) CPU seconds used, as a function of the average working set size, for the programs IEBGENER, IEBCOPY and HASM9.

Better results can be achieved by monitoring a single, known job, as reported by [Bonnes 1986]. The analysis of results for the IEBGENER, IEBCOPY and HASM9 (assembler) programs are shown in Figure 8. They show the expected behavior: the number of page faults per CPU second increases as the average working set decreases. Unfortunately most of the programs do not show such "nice", predictably, behavior.

For a single class model it would be sufficient to know the relation between paging and working set size, as plotted in the Figures 7 and 8. For a multi class model we must know the UIC since it is used to link the working set size of the classes. The UIC, however, is not measured by the standard monitoring tools, so no long term measurement data is available. RMF trace records [IBM 1982] could be used to collect UIC information for specific time periods.

The only acceptable method to *validate* the model presented here is to create a benchmark (test) workload, using a terminal simulator. With such a system, it is possible to perform detailed measurements on a known workload, with a varying number of terminals. This is the method used by hardware manufacturers to compare their systems. Unfortunately, this method requires two dedicated MVS systems to be available for extended periods of time: one to generate the workload, and one to process it.

7. Conclusions

The model as described allows for a reasonably detailed model of the SRM memory control algorithms. In its current form, the model can be used for simple studies on the relations between paging and the memory size of a system. It is easily possible to extend the model to the multi class case, where each class can have its own characteristics. Also, because the model is based on iterative schemes it seems possible to include more of the SRM control mechanisms, notably the domain and performance group concepts. The main problem with the approach is that the parameters, although defined in rather elementary quantities, are hard to obtain from a real workload. We are currently investigating various methods to derive the parameters used from measurement data.

PROFS Capacity Planning Issues

Allan H. Shub
Duke Power Company

ABSTRACT

Capacity Planning in the VM/PROFS environment is, in some respects, less complicated than MVS capacity planning. It is not, however, an exact science, nor can it be applied without an understanding of certain relevant issues and techniques. This paper presents a discussion of some of the more important issues a PROFS capacity planner must address. One of the most significant issues for large PROFS systems is the real storage constraint and the associated limitations imposed on the ability to exploit the capacity of large processors (e.g., IBM 3090-200). Other issues discussed include DW/370 vs. DCF resource requirements and alternative PROFS configurations.

This discussion of PROFS (Professional Office System) capacity planning is not intended to be a comprehensive guide or tutorial. The intent is to highlight several important issues that many PROFS capacity planners must address. Among the issues considered are the relative resource requirements of DW/370 (Displaywrite/370) and DCF (Document Composition Facility), the real storage constraint associated with large PROFS systems and the paucity of data sources and analytical aids.

DATA SOURCES AND ANALYTICAL AIDS

A significant problem facing many PROFS capacity planners and analysts is the acquisition of useful and appropriate resource utilization data. The PROFS capacity planner has relatively simple, homogenous workloads to analyze. It is a relatively simple task to profile the resource requirements for the 'typical' PROFS system. There are relatively few subsystems (e.g., VTAM) and several service machines providing reasonably well defined and limited services (e.g., mail and calendaring). Contrast this to the nightmarish complexity of large MVS/XA online transaction processing systems requiring CICS (with ISC or MRO), IMS or DB2, and several acres of large processors and peripheral equipment. That is the good news.

The bad news is that even though VM systems are generally much simpler than MVS systems, performance monitors, analytical aids and planning tools in the VM environment are severely limited in comparison to the extensive choice available to the MVS capacity planner. VM/Monitor records, for example, are a mere wisp of data compared to SMF/RMF records. Beyond the fact that there are insufficient data, some of the data that are collected are of questionable value. VM/Monitor contains some wonderful anachronisms. Outbound message lengths, for example, are not reported beyond 128 bytes. This is an artifact of TTY terminal protocols. Internal host response times are often estimates rather than measured values. VMMAP (a data analysis facility for VM/Monitor records) and VMPPF (an analytic modeling system also using VM/Monitor data) are supported by different IBM groups in Cary, NC. Both products estimate rather than measure response time. VMMAP and VMPPF employ different algorithms and often yield widely divergent results. (And, of course, each product group contend their estimates are correct.)

As a result of inadequate monitoring facilities, seemingly simple problems can prove to be exceedingly challenging. Suppose, for example, your management requests a functional profile of the 'typical' PROFS user (i.e., how many times per hour or day does this person use notes, calendaring, or document preparation and what are the resource requirements of these functions?). VM/Monitor records contain no useful information with respect to this analysis. The PROFS Programmers Guide for PROFS Release 2.2 (TNL SN20-4668-0) documents accounting exits which may be used to capture the necessary data. The time and personnel resources necessary to code and implement these exits are considerable. Worse yet is the performance caution on the last page, "you risk degrading performance . . . all users will cause your exit to be executed many, many times in the course of a day." Further, so much data can be generated that you may overflow the spool areas. Poorly designed exits, improperly used, could cripple the system. There are third party performance monitors available which will monitor at the exec or module level quite competently (e.g., CMAP). Unfortunately, PROFS is designed with numerous functions incorporated into one module. To circumvent this problem, it is necessary to replace main menu commands with dummy execs, which in turn invoke the PROFS module. Frequency distributions can be generated directly from this data. Resource utilization analysis requires additional post processing (e.g., SAS) to examine the invocations of the PROFS module immediately following the execution of a dummy command.

Of what use is such an analysis? Why jump through all these hoops? If, for example, you are considering replacing DCF with DW/370 it is very important to understand what proportion of the workload DCF activity constitutes. If DCF activity is relatively limited, substitution of DW/370, even if it requires significantly more resources, may be inconsequential and may be implemented with abandon. If, on the other hand, DCF is a major constituent of the workload, a DW/370 substitution may merit a more cautious implementation.

A brief statement concerning performance modeling software: this is one of the few areas where VM support approaches MVS levels. There are two major participants in this area: IBM and BGS Systems. IBM's entry, VMPPF must be recognized because it is from IBM. It is a competent product in most respects and is very easy to use. IBM has a significant advantage in developing support for new products quickly: it has ESP and other interval data to which competitors do not have access. The most significant limitation of VMPPF is the inability to model storage utilization properly, especially with respect to the real storage constraint problem discussed later in this paper. Further, it is not clear what role VMPPF will have in the future. IBM will not disclose how many installations have acquired VMPPF, but it does not appear to have sold well. Enhancements to VMPPF have consisted primarily of support for new products. VMPPF has demonstrated little functional evolution.

BGS System's BEST-1/VM, on the other hand, is evolving rapidly with respect to functional capabilities. Capacity planning software is the lifeblood of BGS Systems and their commitment to support their products is strong and convincing. BEST-1/VM cannot model the real storage constraint, and unlike VMPPF, it cannot effectively model the relationship between PROFS users and the various PROFS service machines. BGS Systems is considering the real storage constraint problem (lack of data may

prohibit resolution). Modeling the linkage between PROFS users and the service machines is expected to be supported by mid-1987.

DW/370 VS. DCF

One of the more interesting PROFS capacity analyses recently conducted at Duke Power Company was the comparative analysis of DW/370 and DCF. The most interesting aspect of this study is that the conclusions differ significantly from recently distributed IBM SNAPSHOT studies (IWSYS Flash F8644, Professional Office System (PROFS) Capacity Planning, 11/28/86). The IBM study indicates that DW/370 document preparation requires approximately 15% less processor capacity than DCF document preparation. The Duke Power study demonstrates that DW/370 requires significantly more processor capacity than DCF (in some situations). More significantly, the Duke Power study also revealed that DW/370 generates significantly more I/O activity than DCF. Total non-paging I/O was 50% to 165% higher and page reads were measurably higher. The results of the Duke Power study include:

- The trivial/non-trivial ratio was consistently between 4-5:1 for the entry/update of the one page documents. However, this same measure is between 1.2-1.7:1 for the entry/update of the five page document with DW/370. The reason for this behavior is the 'TSPELL' function of DW/370.

- The total number of transactions with DW/370 was 17-54% higher than that generated by DCF.

- The total cpu time of DCF was 0-14% higher than that of DW/370 for short documents. For long documents, DW/370 consumed 19-100% more cpu time (100% for document entry, and 19% for document change).

- The total non-paging I/O of DW/370 was 46-165% higher than that of DCF (the higher increases, 91% and 165%, were for the update and entry of the long documents). The primary contributor to this increase appears to be the 'TSPELL' feature of DW/370. Comparing spelling error correction with TSPELL to PROOFREAD (DCF) shows that TSPELL generates five times more I/O activity and three times more processing time.

- The average working set size required for DW/370 was 6-9% higher than that required for DCF for the long document. For short documents, DCF required an average working set size 5-14% greater than that required by DW/370.

- The average number of page reads per transaction observed for DW/370 was 2-15% higher than that observed for DCF for the long document. For short documents, the average number of page reads per transaction observed for DCF was 26-130% higher than for DW/370.

- Although the calculated trivial transaction response time for DW/370 documents was 24-74% higher than that calculated for DCF, the calculated non-trivial transaction response time for DW/370 documents was 54-157% lower than that calculated for DCF. The net effect of this phenomenon is that DW/370 appeared to have more consistent response times.

Refer to Tables 1 and 2 and Figures 1 through 4 for detailed results.

Actual impact of DW/370 on the system will depend on several factors: the capacity of the processor, amount of real storage, the capacity of the I/O subsystem, and the proportion of the workload that will be converted to DW/370. If the system under consideration has an I/O subsystem that is heavily loaded, conversion to DW/370 may entail some risk.

Why do two studies examining the same products produce divergent impressions of the relative resource requirements of DW/370 and DCF? Both studies employed many of the same tools and facilities. The difference in conclusions illustrate the importance of the scope of the study and of initial assumptions, conditions, and limitations on the outcome of the studies.

In their study, IBM adopts a rather limited view of capacity planning and examines only processor utilization. It is assumed that there is no paging, I/O or memory contention. This limited approach is consistent with IBM's USAGE method of capacity planning (VM-USAGE Capacity Planning, GG22-9045-00). It is a useful assumption for comparing the capacity of diverse processors, but it is debatable that it is a useful capacity planning methodology. The higher I/O rates associated with DW/370 illustrate the problem with this assumption. The balanced systems methodology advocated by some within IBM is a better methodology for this problem (Blanced Systems and Capacity Planning, GG22-9299-00).

Both the IBM and Duke Power studies used Teleprocessing Network Simulator (TPNS) to simulate user activity. (TPNS is a testing package that facilitates the evaluation of network and host systems, application software and operating systems without the actual use of a terminal. TPNS uses scripts to generate transactions. While developing these scripts can be a labor intensive effort, it is much less expensive to have one person invest several days developing scripts, than it is to have tens or hundreds of people entering documents from terminals in a coordinated manner for an hour or two. TPNS tests are easily repeatable, and greatly reduce the possibility of human error.)

Perhaps the most significant difference between the two studies is the scripts employed to examine the differences between DW/370 and DCF. The IBM script used only one document. This document had five paragraphs with a total of twenty-three lines. The Duke Power script included entering and updating three different documents of varying lengths (one to five pages) and differing formats. The Duke Power script attempted to minimize the use of the 'ENTER' key. After the completion of the document it was proofread (the same errors were entered in each case), and all errors were corrected. The document was then viewed and returned to personal storage.

Both analyses used PROFS 2.2. IBM collected data from an IBM 4341-P12 with 16 megabytes of real storage operating under VM/SP Release 3.0. Duke Power collected data from an IBM 4381 P-02 with 16 megabytes of real storage operating under VM/SP HPO 4.2.

The differences in the two comparisons of DW/370 and DCF certainly lend credence to the caveat that prefaces most IBM performance and capacity analyses, roughly paraphrased, "these results are reliable only for these conditions and these specific workloads". While we believe that the SNAPSHOT results are reasonable for the workload specified, that workload, by itself, is not a reasonable representation of the workloads found at Duke Power. This leads us to conclude that the Duke Power study may be more representative of the differences between DCF and DW/370 and certainly is more appropriate for our installation. Do your own capacity planning. Do not depend on a vendor or an analyst at another installation to understand your workloads.

REAL STORAGE CONSTRAINT

For very large PROFS installations (1000 or more logged on users on a single processor, or CEC) a new and troublesome problem recently has been recognized: The Real Storage Constraint. The real storage constraint may make the exploitation of an IBM 3090-200 class processor difficult and perhaps impossible under certain circumstances. VM/SP HPO implements 24-bit addressing archi-

tecture which permits addressing up to 16 megabytes of real storage. The CP portion of HPO is implemented without dynamic address translation (DAT), and therefore restricted to addressing the real storage below the 16 megabyte line. Areas referenced by CP must also reside below the 16 megabyte line. These areas include trace tables, control blocks (FREE STORAGE) and user pages (DPA).

Free storage is not pageable. Each virtual machine in the system requires as much as three pages of free storage. Free storage contains the page and swap tables as well as other control blocks. The VM/SP HPO Planning Guide and Reference (SC19-6223-6) states that a modest virtual machine configuration requires less than one page of free storage. Based on this estimate, 1200 PROFS users would require about five megabytes of free storage. Unfortunately, the IBM estimate is unrealistic. Two or three pages is more realistic (at Duke Power, it requires approximately 2.6 pages of free storage per virtual machine). At approximately three pages per machine, 1200 machines require 3600 of the 4000 pages below the 16 megabyte line. (Figure 5 illustrates the usage of real storage below the 16 megabyte line.) Remove another 400 of 500K for the nucleus, and not much is left for user pages (DPA). The enormous fixed storage requirements of large VM systems effectively limits the exploitation of large IBM 3090 processors with respect to workloads that have a large number of users (e.g., PROFS). Much of the power of an IBM 3090-200 may be wasted if large numbers of users cannot be logged on because of the real storage constraint. An IBM 3090-200 has the processor capacity to support 2000 or more active PROFS virtual machines, but until the real storage constraint is resolved, it may be limited to 1200 or so logged on.

The ultimate solution is, obviously, to implement 31-bit addressing. VM/XA is the VM operating system that supports 31 bit addressing. VM/XA's control program can address two gigabytes, and the real storage constraint simply does not occur. The current implementation of VM/XA (VM/XA System Facility) is a limited operating system; or as IBM so delicately states, it "lacks some of the functional richness of HPO." That means that it does not support CMS (or PROFS) among other things. To use VM/XA SF as a solution requires VM guests and the performance trade off associated with guest machines (90% of native performance for the preferred guest and leftovers for the other guests). PROFS communities may may also have to be split to separate VM guest machines (the real storage constraint applies to the guest systems). General availability of full function VM/XA SP is not until March, 1988. Release 1 will not support native VTAM; that support will be in Release 2 (1Q 1989).

Assuming the VM/XA SF solution is not appealing and the problem must be addressed before the availability of VM/XA SP, there are a variety of options that will provide limited relief for the real storage constraint. Managing VM/SP HPO Real Storage Constraint Below the 16 Megabyte Line, (GG66-0261-00) documents 31 actions that may be taken to relieve the real storage constraint. (Also refer to VM/HPO Performance Tuning Guide (GG22-9392-01) for additional tuning suggestions). The single, most effective action is the installation of VM/SP HPO 4.2. HPO 4.2 is much more aggressive in migrating page and swap tables of inactive users. The only criteria for migration in HPO 4.2 is that page and swap tables comprise at least 12% of unextended free storage, and it is easily met. At Duke Power, implementation of HPO 4.2 reduced free storage requirements by approximately 2.5 megabytes for 850 logged on users. VM/HPO 5.0 will further reduce free storage requirements.

The PROFS environment can be changed in several ways to better exploit the improved migration of page and swap tables offered by HPO 4.2. (These changes may reduce the function or convenience of PROFS and may be unpalatable to portions of the PROFS user community.) These changes include:

- increase the PROFS timer interval as much as possible. Without modifying PROFS, the maximum value is 999 seconds (or 16.7 minutes). The only function affected by this change is REMINDERS. The benefits of increasing the timer interval are significant. In addition to increasing the number of users considered inactive and eligible for migration, significant reductions in paging and swapping may be realized. At Duke Power, the interval was changed from one minute to five minutes. Swapping and paging rates decreased by one-third and one-fourth, respectively.

- in later releases of PROFS, the interval timer may be selectively disabled. To minimize page/swap activity and free storage requirements, disable the timer for all machines except those having an OFS $remind file at logon and enable the clock for any user who envokes the reminder function.

- implmentation forced logoff. Timeout will release additional free storage. Even if an inactive virtual machine's page and swap tables have been migrated, approximately one page of free storage remains resident in real storage. At Duke Power, 850 to 900 users are usually logged-on at any given time. Analysis of VM/Monitor data indicates that only 350 to 400 (approximately 40%) of the logged on users are active during a 15 minute period (i.e., performing some task other than the servicing of timer pops. Refer to Figure 6). Forcing off those machines that are inactive would release an additional 1.5 to 2 megabytes of free storage. The timer interval must be longer than the timeout interval, otherwise no virtual machines will be timed out.

- circumvention or resolution of the real storage constraint may only provide limited expansion capabilities. There is reason to believe that VTAM in the VM environment can support only about 1400 concurrent users. Detail of this constraint and possible plans for resolutions are not generally available.

PROFS capacity planning is more of an art than a science. Improvements in products such as BEST-1/VM and the availability of more monitoring facilities offer hope that this situation will change in the not too distant future. It cannot be overemphasized that it is imperative that performance expectation and forecasts must be based on workloads and conditions similar to those which are anticipated.

VM PERFORMANCE - TOP DOWN THAT WENT BOTTOM UP

Mary Sue Dickerson
United Airlines

ABSTRACT

The plan was to do hardware planning, bottleneck analysis, and response time profiles for a currently running VM system. This goal was to be accomplished in minimal time and with only 'part' of a person. To achieve this no time could be spent 're-inventing the wheel', so a model was purchased to predict the effects on response time of changing hardware. A data base was developed using the model's output to record changes. But the VM system analyzed was not primarily a CMS machine, and the model would not converge with measured data.

This paper describes some of the top down events that started with a 'sophisticated' VM model but led all the way back down to the 'raw' monitor data. Some of the things learned about VM and the monitor data on the bottom up ascent will be discussed. This paper is specific to VM with the aim of broadening viewpoints for anyone involved in the performance of a VM System.

1. PURPOSE

The purpose for writing this paper is to describe some analysis which can be done easily and without a big expenditure in time or money. At first the monitor data seemed untouchable, but once the initial barrier (partly the sheer volume of data) was broken, a world of opportunity unfolded with little effort. However, since starting from scratch is justifiably not in vogue these days, a background explanation will be given first. This paper will not describe a super in-house developed performance reporting and database system for VM to replace VMMAP, but simply a way to have control over the monitor data for flexibility. This paper will also not describe differences in the various VM systems, but will assume the HPO 3.6 Version of VM.

2. BACKGROUND

A formal capacity planning and measurement effort was made for an existing VM system with about 350 users logged on and 20-25 guest TPF (Transaction Processing Facility) operating systems. TPF is a streamlined operating system which processes on-line transactions quickly. The VM system was used as a development system for TPF and complaints of slow response times were frequent. The system's hardware was primarily back-up for the online system. However, to support these testing requirements, capital expenditures would need to be made. The planning effort was to make sure the money was spent most effectively.

The first step was to purchase VMPPF, a VM model available from IBM. The intent was to validate a model of the current system to obtain a wait/service profile for an existing transaction. The second step would be to alter the system hardware and model its effect on response time. The problem was that the model did not converge due to swapping conditions. In other words, the model was saying our currently running system couldn't possibly be running. But it was.

Disappointment was also experienced by the manual effort to relate the 300 disks (actually more, except monitor did not report on them) to workload classes. More support from the vendor could probably have resolved some of the problems, but this didn't happen. The last recommendation before the model was put on hold was to model CMS with two or three of the TPF systems and block off the resources of the remaining TPF systems used with the 'dedicated batch' facility. The model converged but this meant about 60% or more of the system was blocked off with still no trusted value for transaction response time.

After this experience there was not much support to purchase another product from any vendor. Besides this would have meant a nine to twelve month delay before the software was approved, purchased, and installed. Then training would be required for getting up to speed for the new product. This was not a thrilling prospect while users were complaining daily. The immediate step was to find out how 'bad' a slow response was by being able to enumerate response times.

3. RESPONSE TIME - A MUST

The problem of measuring response times was solved by modifying a service machine which most TPF transactions go through for a CRT interface to the TPF system. The transactions are time-stamped in microseconds as they enter the service machine and again as they leave. These data are then spooled to a reader file, read by SAS, and a response time distribution for each TPF system is saved in a data base. A report by response time distributions was found to be both more consistent and representative than a straight average because a few large response times frequently inflated the average.

The reported response times did not include the trivial CMS response time or any control unit contention (a network was not involved), but the most variable portion of the total time had been captured. Since the virtual user identification was retained in the response data, a user complaining of slow response times could be handed a report listing all his transactions with their respective response times. Handing a user a personal list of response times was dramatic and proved to be valuable in establishing a starting point.

The next task was to identify components which were slowing down the responses and break them up into wait and service components. The methodology used will be termed 'contention analysis' [1]. Although less sophisicated than a model, the method was cheaper in terms of money, people, and time, but yet effective in identifying the VM system capacity constraints. The main drawback is not being able to automatically project response time changes as a result of new hardware. David Potter with the IBM research Laboratory in Yorktown Heights was a great help and many of the following ideas were his.

4. CONTENTION ANALYSIS

The first big breakthrough came when it was learned how to read the monitor records. They are easily read with REXX (VM System Product Interpreter) and the few lines of code to read them have been included in Appendix A. Like a 'kid in a candy store', all the data available create the temptation to re-write VMMAP or spend time and computer resources databasing everything. But the goal was to look at small amounts of data for specific purposes. In other words 'keep it simple' and 'change will be the norm'. One important exception was to put basic system variables such as CPU utilization, paging, and I/O, with the collected response times on a one page management report. SAS was used to read the records created by REXX and to maintain a database.

The contention analysis evaluated various wait states for in-queue users. Most of these values came from the user monitor records (code 400). The wait components were first broken into eligible, in-queue, console function wait, and idle. The in-queue waits are divided into CPU, I/O, page, swap, deferred function, instruction simulation, terminal I/O, run user (not yet dispatched), PSW, and unknown wait. The REXX code to break users into various waits is included in Appendix B. A SAS timeplot then shows these waits for each interval throughout the day.

The percentage of in-queue users in each wait state can be calculated for more specific analysis. SRM tuning parameters can change most of these waits (for example minimum working set size may affect eligibility); however, they will not be addressed further in this paper. Each of the in-queue waits is now examined.

CPU wait (CP) - The workload or hardware needs to be adjusted. A graph of active users by the percentage in CPU wait will give a good indication of the limit for the CPU.

I/O wait (IO) - The monitor device (600-602) records or VMMAP will give an idea of busy devices. Actually this implementation reads the monitor records and lists every occurrence of a device or control unit queue throughout the entire day. Devices or paths with frequent queues are then suspected if I/O wait is significant. I/O contention may occur even if I/O wait percentage is low due to serialization within the application, and once an I/O has been started, the user is no longer considered to be in I/O wait.

SWAP wait (SW) - If swapping wait is high, the most likely solution is to upgrade DASD or rearrange the DASD subsystem.

Deferred Function (DF) - Deferred function waits are caused by a resource within the Control Program that must be serialized. Further examination of deferred function waits can be done by estimating the percentage of time each lock is busy. Taking the square root of the percentage of spin time per second for each lock will give an approximation of how long each lock is active. A separate lock report estimates the time active for the system lock, the freelist lock, the run list, the timer request lock, dispatcher lock, I/O lock and the real memory lock. The busiest of these is likely to be causing the deferred function wait.

Instruction Execution (EX) - If this wait is high, the instructions which are being simulated most often will offer clues on what is causing the wait. A separate report lists the number of occurrences for each privileged instruction execution per second for each interval throughout the day.

Terminal I/O Wait (TIO) - This is a special case of the privileged instructions wait in which terminal I/O is being waited on. This is determined by the TIO bit being on at the same time the user is in instruction execution wait. A high percentage of users in terminal I/O wait may be caused by many full-screen reads/writes instead of reading only changed data.

Run User (RU) - This is a user who hasn't yet been dispatched and so cannot technically be counted as CPU wait.

PSW Wait (PS) - This is a user which has entered a voluntary wait state and, at least for the first-cut, does not necessarily represent badness. For this reason the number of users in PSW wait was subtracted from the in-queue users for the denominator when calculating the percentage of in-queue users for each of the above wait states.

Unknown Wait (UK) - Finally if a user is in-queue but failed to fit in any of the above wait states, the state is called unknown. This should be the exception.

The above information is readily available in real-time with the 'IND POS' or the 'IND Q' command and has proven to be an effective measure if the system has just bogged down. These displays give the numbers in most of the above wait states and response is much faster than going into a 'real time' monitor.

5. Real Storage Indicators

Storage was the next resource looked at closely since VM is generally very slow when 'serious' problems occur within its storage subsystem. High activity on the real-memory lock mentioned before as a deferred function wait will give a clue to storage problems, but other variables need to be examined as well. The VM system which prompted this paper had a high number of page frame moves above and below the 16 Meg boundary. The cause was later determined to be from a high usage of IUCV (Inter-User Communication Vehicle).

Paging and swapping in VM must happen quickly if response times are not to suffer. Tetzlaff and Beretvas [2] have written a good paper summarizing paging in VM, so only a couple of sentences will be restated here. When more real page frames are needed, the first place VM looks is the non-interactive queue for users which have exceeded the SRM value SWPQTIME. Next the flush list is made available (these are users' pages which were not referenced during the last queue stay). The next place to get page frames is from the logically swapped users, first the non-interactive and then the interactive that are currently not in queue. The last resort is a corescan which takes pages from in-queue users. This presents a problem for VM and thrashing can occur if this stealing happens often. The following variables, page frame steals per second, pages examined for stealing, and full corescans per second, give an indication how much page stealing is hurting the system.

Since the storage service time depends on how fast pages can be brought in and out of memory, the speed and size of primary paging is important. A rule of thumb that 80% of the active users working sets would fit in the primary paging area was used to determine the best size for primary paging. However, the value of 'active users' is actually a function of time. The longer the time period, the larger the number of active users hence a larger total working set size. Active users can be reported on for any time frame equal to or larger than the monitor interval. This implementation used a five minute time frame to determine primary paging size. Active users are easily counted in REXX from the user records by using 'associative memory' or 'content addressable' features of compound REXX symbols (arrays). This implementation calculates several active user counts rangeing from a time length of each monitor interval to an hour.

6. CONCLUSION

What was learned from all of this? A purchased model of VM would not answer many performance questions for this particular system. This system was special in the sense that most of its workload consisted of 25 TPF operating systems and VM did not see enough detail of what was happening within each system for the model to yield accurate results. Using measured response times along with data from TPF system collectors, enough detail may be able to be supplied to the model to make it converge, but the manual effort is great.

The knowledge that contention analysis for an existing VM system could be preformed without a great effort provided the motivation for writing this paper. The analysis which was performed on a currently running VM system has been documentated. However, there is still the very big short-fall of not being able to project what changes will do to response time. Contention analysis will identify hardware shortages, but a model would be useful for projecting response times with these hardware changes. To make this model reasonable to use, more data will be required about the guest operating systems.

END-USER RESPONSE TIME MEASUREMENT - NOT THE FINAL SOLUTION

Per Futtrup
Morten Panduro
Bent Vestermark
Scandinavian Airlines System

ABSTRACT

In recent years efforts to secure the end-user a proper response time have had a tendency to focus on tools for measuring this. Once the tool is in place you will find that the figures obtained only tells you whether or not they are acceptable. If they are not, you will find that you need further tools to pinpoint problem areas. Therefore tools for problem determination should be based on systems that track parts of the total system instead of end-user response time.
The tool for end-user response time measurement is still an excellent tool for management reporting, and to ensure that end-user response time is acceptable when none of the other tools reports any problems. In this session we will present the principles of tools in use at our installation, and our experience with these tools.

1. LIMITATION.

At our installation we work with three concepts to characterize the service delivered to the end-user:

- response time
- unavailability
- instability

Instability is the grey area between normal operation and unavailability, which includes things like retransmissions, load regulation and fallback mode.
These three concepts are rather well defined from a technical point of view, but are very difficult to communicate to the users.
The question raised by a user which above all made us aware of this problem was the following:

> 'where is the limit between long response times and unavailability'.

With hot standby for the communication computers a stop normally takes less than one minute, and with a non technical user this may look like long response times. This problem remains unsolved at our installation.

In this session we will concentrate on tools used to secure the end-user an acceptable response time. Although instability will influence response times, we will not cover that, and we will not cover response times in fallback mode either.

2. INTRODUCTION.

The high importance of today's online systems has caused a great interest in service delivered to the end-user, and thereby also in tools for end user response time measurement.

We have had such a tool in use for some time, and have found that there are several problems involved, if problem determination is based on such a tool. Some of them are:

- Several components are involved in the path from the end-user to the application: terminal line, communication computer, trunk line, etc. There are a lot of places to search for the reason.
- In our company three different departments are involved, and as Murphy says, 'If more than one person is responsible for a miscalculation, no one will be at fault'.
- If the reason for the problem is in the application or communication computer, you may have thousands of users on your list with response time problems.

We find it better to prevent than cure, and therefore we think that tools used for problem determination should be tools that track and report on individual components in the system, and not on complex entities, which the end-user response time is.

2.1 SPLIT OF SERVICE LEVEL.

This means that the service level for end-user response time must be split into service levels for parts of the system, not necessarily for each component. We have split our service level into three parts, as can be seen in figure 1.:

- Host.
- High Level Network which includes interface, front end, trunk line, and remote concentrator.
- Low Level Network which includes terminal line, controller and the terminal.

Communication with users is still done in terms of end-user response time. The split was done as part of an effort to improve service through a better motivated staff within the DP departments, and it is not without problems.

It is rather easy to define host service level for an application, but fulfillment of this may only fulfill end-user service level for a part of the total user group. some users may have a worse service because of the way they use the application.

Host service level is normally defined for peak periods, e.g. peak hour, and this period is in most cases well defined and well known. As you move out from the host, the peak periods will vary more and more, especially if you have a world wide network. This means that you do not have one peak hour any more, but a lot of them.

The split has the advantage that each individual DP department has its own goals to fulfill, and by that also the possibility to generate exception reports for their area. Also they can generate reports showing their performance against their obligations, and by that motivate staff to improve service where needed.

The system highly simplifies the problem determination, because reports are sent directly to the responsible department, and only reports needed are generated.

2.2. SPLIT RESPONSIBILITY.

In some installations the DP department is only responsible for parts of the total system between the end-user and the application, although they may be responsible for the end-user response time. In these cases it is highly important that they know what service their part of the system is giving.

Figure 2. shows an example where their responsibility ends at the connection between the terminal concentrator and the foreign system.

Figure 3. shows an example where a foreign system is put in between the data department's remote concentrator and terminl equipment. In this case measurement of end-user response time (in our own equipment) in combination with knowledge about our own service, gives the possibility to report on service received from the foreign system.

We have all abovementioned cases in our total system.

2.3. MANAGEMENT.

Comments to management reports based on measurements of end-user service are more easily given if each department has its own follow-up system with historic exception reports giving:

- the reason for the problem.
- what was done to remove the problem.
- what was done to ensure that this will not happen again.

In the following we will present the tools in use at our site. It should be mentioned that the network basis for this session is a network based on UNISYS hardware and software.

3. END-USER RESPONSE TIME MONITOR.

When we implemented new terminal equipment in early 1986, it became possible to measure the real response time at the end-user. The terminal equipment can save measurements against 4 different applications. For each of these applications we have 4 response time limits with corresponding counters, plus an overflow counter that counts transactions with response time higher than the highest limit. Besides that we have a counter for total resonse time. The response time can be measured in three ways, from pressing the send button until first character appears on the screen, or until ACK received on input message (not end-user response time), or until cursor is released.

3.1. PRINCIPLES.

We only had a few measurements of end-user response time before this equipment was installed. During installation we decided upon the following principles:

- The new equipment should not be installed at strategically important places until it was reasonable stable.
- All terminals in a work area should be exchanged with the new type to avoid confusing the users.
- To get as broad a picture of response times as possible, we exchanged equipment both in various geographical areas, and in areas where different applications were used.
- The points chosen in the initial phase are used in monthly reports to be able to compare figures from month to month.
- The applications to be measured for a terminal shall be:
  application 1 - most used application.
  application 2 - decided by the user.
  application 3 - decided by the user.
  application 4 - all other transactions.
- Response time limits were universally set to 3 sec, 4 sec, 7 sec, and 12 sec.
- Response time definition was universally set to 'release of cursor'.
- Collection of measurements to central site is done once every 24 hours. They can be collected more frequently if needed.

3.2. USAGE.

The tool is mainly used for the following:

- Reports on service to management and users.
- To determine if the end-user service level is fulfilled when service levels for all parts of the system are fulfilled.
- As mentioned above to control service delivered from a vendor.
- To help users complain about bad response times. Measurements can be displayed at the users terminal, so he can determine whether he gets a service according to service levels.
- To help technicians to see the effects of certain changes, e.g. if traffic is sent through a statistical multiplexor.

3.3 REPORTS.

We try to satisfy management's and end-user's need for information through our monthly reports. We have no fixed reporting structure for technicians, so their need is covered through adhoc reports. The monthly reports consist of two parts, a graphical part which reports on the initially chosen points, and a text part containing data about all terminals being measured, today about 850. The graphical part consists of two types of reports.

The first report, shown in figure 4, gives an overview of a month's service. The left part describes how large a percentage of the terminals had fulfilled service-levels. The right part shows how much the total average response time deviates from present goal. Application MP had a total average response time half a second better than goal, but servicelevels was only fulfilled for 50% of the terminals.

The second report, shown in figure 5, gives response times per application, and shows the development over the last 6 months. The left part gives response time distribution within 4 limits. The right part gives the average response time for the whole month, and for the worst day during the month. Besides these reports we have a menu driven interface against the database, which gives our front office and others access to detailed data and allows them to compose reports in various ways.

The service levels mentioned above were set internally in the data department during implementation of the monitor, due to lack of service levels agreed with the users. Agreements have later been reached for two major applications, and they say that 90% of the transactions shall be below 4 seconds.

4. HOST.

The definition of host response time is the time from message receipt on input queue until the response is placed on output queue. Service level is defined for two of our most important applications, and says that 90% of the transactions shall have a host response time below 1.3 seconds.

Daily monitoring of response times are done for applications and transaction codes, but not for individual users or groups of users.

Figure 6 gives an example of a report from the host response time monitoring system.

5. HIGH LEVEL NETWORK.

The service level for response time in the HLN is that 90% of the transactions shall be below 0.3 seconds. The response time in this part of the system is defined as the time from when the input message is totally received from the terminal line until the output message is placed on the queue to the terminal line, minus time spent in the host. The service level is in principle only defined for two major applications. The average message length influences the response time, but with the line speeds and message lengths currently used in our installation (minimum line speed 64 KB and average output message length 250-600 characters), this will be valid for almost all applications.

Follow-up includes communication computers, trunk lines and interfaces to hosts. We have further implemented a special response time monitor for the high level network.

5.1. COMMUNICATION COMPUTER FOLLOW-UP.

Continous check of communication computers is based on CPU and buffer utilization. Number of open/close sessions and disk accesses are also important for the performance. Data for this are collected continuously, but only used on an ad-hoc basis, because unfavourable development of these figures will be reflected in the CPU utilization.

5.1.1. CPU UTILIZATION. Monitoring of CPU utilization consists of checking two things:

- that the load on the CPU (traffic) develops according to plan.
- that the capacity of the communication computer (maximum traffic that can be handled per second) does not decrease, e.g. because of changes to software.

Two reports are produced and checked daily. The first report, shown in figure 7, is a plot containing the previous day´s observations with CPU IDLE % along one axis, and traffic in messages per second along the other. This plot shows traffic load during the day, and whether or not abnormal incidents have happened. On this particular plot a group of observations can be seen down to the right, representing a load much higher than expected. A detailed analysis showed that the traffic between the communication computer and the development system was 50 segments per second higher than normal, probably caused by a looping message. In this case the maximum load stayed below the maximum capacity (the reference line at 15% CPU IDLE) so no harm was done to the users.

The second report, shown in figure 8, gives the capacity of each communication computer calculated on that day´s observations. Further, the peak traffic rate is shown. We operate with two limits for the CPU. The first at 30% CPU IDLE is the planning limit, and is used when plans are made one to three years ahead. The second is at 15% CPU IDLE, and this limit represents the maximum usable capacity.

Another report, shown in figure 9, is produced monthly. This report shows both utilization of the computer and capacity in messages per second this month compared to the previous months, by means of regression lines. It can be seen in this example that capacity has been about 15% lower than 6 months before, but that it is moving back up again. The reason was mainly implementation of new discs, but tuning has been done so the capacity will come back up where it was before the implementation.

5.1.2 MESSAGE BUFFER UTILIZATION. Control of buffer utilization simply consists of ensuring that an adequate number of buffers are available at all times.

The report shown in figure 10 is created daily, and shows average and minimum number of free buffers in 10 minute periods (recording interval) throughout the day. The figures should be above the reference line at 3000 free buffers.

The smallest daily figures for average and minimum number of free buffers are collected and presented in the monthly report shown in figure 11. This report covers a period of 3 months.

5.2 TRUNK LINES AND INTERFACES.

Delay in these parts of the system depends on line utilization, line speed and message length when hardware and software (protocol) has been selected.

Reported service level for the high level network is partly based on experience from the response time monitor in the high level network mentioned below, partly on calculations of delays in the present configuration.

Maximum utilizations from these calculations are used in the follow-up system for the lines. Experiments have shown that we can go even higher than these utilizations without significant impact on service.

The maximum utilization has been supplemented with a warning limit placed 10% lower than the maximum, to have time for corrective action before service levels are exceeded. The follow-up system compares daily recorded peak trunk utilizations with the limits, and prints out an exception report if the alarm limit is exceeded. The reports can be printed on adhoc basis too.

Figure 12 gives an example of such a report for a trunk line. The alarm limit is set to 60%, and the maximum capacity to 70%. The plot shows the range of the three highest observations per day measured over 10 minute periods, both for in-going and out-going traffic. Exception reports are created based on the largest traffic in each direction, because the trunk line is a full duplex connection. The traffic has not passed the alarm limit in the report shown.

5.3 HIGH LEVEL NETWORK RESPONSE TIME MONITOR.

Early in 1987 we got the opportunity to measure response times in the high level network. This monitor can measure against up to 8 destinations, and it is based on synthetic messages instead of real traffic.

We measure against our 5 main hosts and our two most important applications. Each node in the network sends out messages to the above mentioned 7 destinations, and measures the time from when the message is sent until it is received again. The message turns around in the communication part of the host when hosts are measured, whereas measurement of applications are done by executing the same transaction again and again.
It should be noted that this software has a low priority in the communication node, which means that under abnormal conditions it will not be executed.

The resonse time limits are, after a couple of adjustments, set to 0.1, 0.3, 0.7, and 2 seconds. In reality we have one more limit, because the system times out after 20 seconds, so messages with a higher response time are counted as ´no response´. This means that the overflow counter contains messages with response times between 2 and 20 seconds.

Before implementation of this tool we had calculated the average peak response time to be 0.285 seconds. The first month we measured an average response time of 0.257 seconds. This was measured off peak, and around 30 milliseconds has to be added to adjust for message length.

The reports produced from this system correspond mainly to those mentioned under end-user response time, with a graphic part and a text part.

The graphic part has one page per main host or application (figure 13), which shows the response times for the previous month. The left part shows the response time distribution from remote concentrators against the PRODC host (plus ALL which is the distribution of all response times measured). The right part shows average response times for the whole month and for the worst day.

The text part also gives response times from front ends, plus the number of messages which is the basis for the calculations.

6. LOW LEVEL NETWORK.

The low level network is the only part of the system where we cannot directly measure the response times. We can estimate these by subtracting host and high level network response times from response times measured by the end-user response time monitor.

The service level agreement, which presently exists only for the two major applications, says that 90% of the transactions shall have response time in this part of the system less than 2.4 seconds. This means that half of the total response time may be caused by the low level network.

The definition of response time here is time from depression of the send button until response is presented on the screen and the cursor is released, minus the time from when input is totally received by the communication processor until a response is placed on output queue in the processor again.

Follow-up in this part is based on the fact that line utilization can be translated to response time, when we disregard instability like retransmissions.

The follow-up system consists of two parts:
- continuous control of line utilization
- modelling to estimate maximum acceptable line utilization when service levels shall be fulfilled.

6.1. LINE UTILIZATION.

The continuous control of line utilization is similar to the system mentioned under trunk lines and interfaces. The maximum and alarm limits vary more because of differences in configurations. The system has only been used for a few months, and we may have to change the criteria for creation of exception reports. Reports are created when the three highest observations for a day (based on 10 min. periods) pass the alarm limit; however this criterion may change based on experience.

Figure 14 shows an example of an exception report. This report was produced in the initial phase of the system, and has only one limit set very roughly. This was a line with much too high a line utilization.

The follow-up is based on total traffic on the line (characters per second), not subdivided in any way e.g. per application, and assumes that no major change of message length will occur (application programmers are expected to warn us about that).

6.2. MODELLING.

Maximum and alarm limits are estimated by means of a modelling tool when existing lines have to be reconfigured or when new lines are planned.
More detailed information is needed for this job than that used in connection with control of line utilization.

The report shown in figure 15 is created when lines are reconfigured. One week's data are the basis for the report and it gives the three highest observations during that week, based on total characters for the controller. The report can also be created at times where the line peaks.

The traffic to and from the controller is only subdivided into equipment types (equ), but we may have to subdivide it into applications too in future, because service levels are agreed per application.

The information is put into the model, and it is decided what action to take, normally either increase of line speed or decrease of traffic by moving one or more controllers to another line. After that, the maximum line utilization is determined.

For new lines traffic may not be available, and therefore the figures are estimated based on knowledge about what the terminals will be used for.

6.3 CONTROLLERS.

One assumption in our modelling work is that the controllers cause no delays, but increasing line speeds, new communication computers, and increased use of complex functions like cursor positioning and protected fields have changed this.

We saw the problem first time 2 to 3 years ago, when an increase of line speed caused longer response times. The reason is that the microprocessor in the controller is too slow, and we are for the moment running some load-tests, to find the configuration limits we have to observe to ensure that controllers cause no delays.

7. COMPARISON OF MEASUREMENTS.

To compare figures from the various tools we have to keep in mind what is measured and over which periods. All tools used for problem determination are based on peak periods, whereas response time monitors are based on 24 hour periods. The following summarises that:

Tool	what	period
End-user response time measurement	transactions per terminal and application	24 hours
Host response time measurement	transactions per application	peak hour
High level network response time measurement	sample messages (length 10 chars)	24 hours
Communication computers	cpu and buffer util	10 min. periods all 24 hours
Trunk lines and interfaces	all user traffic	10 min. periods all 24 hours
Low level line utilisation	all user traffic	10 min. periods all 24 hours
modelling	several possibilities	peak hour

The end-user service level, 90% below 4 seconds, are defined for 24 hour periods, so this fits with the response time monitors.

The goal for each DP department involved is defined as a percentile, so we must be lucky if the end-user goal is fulfilled when all three parts are fulfilled. To specify the goals as percentiles in stead of averages has made the whole job more difficult, but we had no influence on that decision.
The modelling tool used for the low-level network can only report average response time, so we have no knowledge about percentiles here. To overcome this problem we have looked at several places with end-user RTM, to estimate an average low level network response time which can replace the percentile.

In the following we have specified some measurements. We have specified average figures, the only figures available for the low level network, to be able to compare with the end-user RTM, but the following is valid:

Host: 90% or more is below 1.3 seconds, when the average is below 1.0 seconds.

High level network: 90% or more is below 0.3 seconds when the average is below 0.3 seconds.

The partial figures represent different things, so the sum of these will not add up to the average shown under end-user RTM. We expect the sum to be higher because the host figure and the figure for the low level network is based on peak periods.

line S1J against the CSS application

partial figures.

date	host	high level net RTM.	low level net. modelling	
	avg.	avg.	avg.	%util.
27apr87	0.59	0.24	1.74	18.2
28apr87	2.05	0.25	1.42	13.5
29apr87	0.62	0.25	1.44	10.0
04may87	1.04	0.18	1.33	13.4

total figures.

date	end-user RTM.		sum of partial figures.	difference
	%<4	avg.	sum	%
27apr87	95.2	1.97	2.57	30
28apr87	94.6	2.07	3.72	80
29apr87	96.6	1.93	2.31	20
04may87	95.3	2.03	2.55	26

In this example the sum of the partial figures is 20%-30% higher than the end-user RTM, except 28apr87. This day the host had a problem causing the average host response time to be 2.05 seconds, but the end-user RTM shows that users on this line was not affected by the problem.

line D47 against the CSS application

partial figures.

date	host	high level net RTM.	low level net. modelling	
	avg.	avg.	avg	%util.
04may87	1.04	0.19	5.28	35.2
05may87	0.64	0.16	5.01	33.7
11may87	0.63	0.17	4.39	29.7
12may87	0.54	0.23	4.11	27.0
13may87	0.65	0.20	4.20	27.8

total figures.

date	end-user RTM.		sum of partial figures.	difference
	%<4	avg.	sum	%
04may87	70.3	3.75	6.51	74
05may87	73.4	3.47	5.81	67
11may87	72.9	3.43	5.19	51
12may87	71.1	3.62	4.88	35
13may87	72.4	3.48	5.05	45

There is a rather big difference for line D47, but that is because line utilisation was so high it caused a great difference between peak and off peak figures.

8. Conclusion.

We find that the end-user response time monitor is not mandatory to be able to obtain and maintain a certain service level for the end-user. We felt very uncertain about this until we got the tool, but we are now convinced that we can base our problem determination on the partial tools.

These tools are less accurate than the response time monitor because of certain approximations, but we find the results acceptable. One problem though is that users do not trust modelling in discussions about service, but we hope that this problem will disappear when we consistently deliver decent service, as there hopefully will be no reason for discussions.

Reports on measured end-user response time for all terminals cannot be produced, so this system do not satisfy management's need for that.

Figure 15.

DETERMINING END USER RESPONSE TIME USING NLDM.

Michael W. Yount
Rohm and Haas Company, Philadelphia, PA 19105

ABSTRACT

Network Logical Data Manager (NLDM), now a part of Netview, is a software tool that collects end-user response time statistics from a Response Time Monitor (RTM). The RTM is a hardware feature that can be placed on 3274 control units and comes standard on 3174's. Unlike some other network software tools, NLDM reported response times are measured, not calculated response times.

The data collected by NLDM can be made available in several different ways. Of specific interest in this paper will be the ability of NLDM to write an SMF (type 39) record. The MICS SNA Network Component, SAS* software or some other tool may be used to extract the data from the SMF record. The data can be used to identify problem areas in the network, to report response time information to management or users and to set end-user response time objectives.

INTRODUCTION

Network Logical Data Manager (NLDM), now part of Netview, is an IBM program product. It requires Network Communication Control Facility (NCCF) and Virtual Storage Access Method (VSAM) as prerequisites. NLDM runs as an application program under NCCF and can collect and display three types of session data for System Network Architecture (SNA) environments:

- Session Awareness data
- Session Trace data
- Session Response time data.

This paper will discuss the area of response time data collection.

HOW NLDM WORKS

NLDM collects response time statistics from a Response Time Monitor (RTM). The RTM is a hardware feature that can be placed on 3274 control units and comes standard on 3174 control units. The control unit collects the response times into ranges of time that are specified when you define the performance classes in your NCCF parameter library (see List I).

The VTAM naming conventions your shop uses for applications, control units, and terminals plays an important role in the identification process. For example, our shop uses a naming convention for control units and terminals where characters 2-4 of the name identify the plant or office location, making the mapping of terminals to location a simple task.

Within the definition of performance classes you can set how the response time is to be measured. This is the time from when a transaction is activated (e.g. the ENTER key is depressed) until a response is received. This may be defined as:

- FIRST - When the first character of the reply from the host is received at the user's terminal. This is the default definition if no other is specified.
- CDEB - When an SNA 'change direction' or 'end bracket' is received at the user's terminal. (Because we use a significant amount of Session Manager, we found this to work best in our environment).
- KEYBD - When the user's terminal keyboard is unlocked.

NLDM collects the response time data from the control units by the issuing of a "COLLECT' command or at session termination. By taking advantage of NCCF services it is possible to issue the COLLECT command automatically using an NCCF timer-initiated CLIST. We found it desirable to collect the response time on 15 minute increments to correspond to RMF intervals.

NLDM can be configured to report response time in three different ways:

1) It will display response time trends and summaries during the day by collection intervals for a selected terminal. This can be useful in determining response degradation.
2) For terminals attached to a control unit with the RTM feature it can be configured to display the response time for individual transactions on the user's terminal.
3) The response time data is written out to an SMF record where it can be extracted and used for analysis, trending or for establishing and tracking end-user response time objectives. This can be accomplished through the use of an analyst created SAS program, by acquiring the SNA Network Component of the MICS data base or using code from Merrill's MXG package.

EXTRACTING THE DATA FROM SMF

NLDM creates type 39 (HEX '27') SMF records. The records created by NLDM may be any one of the following types:

Records	Identification Number
. Session start	3
. RTM collection	1
. Accounting and availability	4
. Bind Failure	6
. Combined	5
. Session end	2

Only the RTM collection, Combined and Session end records contain response time information. Some of the types of information that can be extracted are number of transactions measured, five response time collection buckets (user defined - see List I), the VTAM name for the application, the terminal ID, the performance class name (user defined - see List I), etc. Once the data has been extracted from the SMF records, it can be manipulated as required. For example, Table 1 shows a days worth of data by performance standards.

The first letters of the performance class (NSVPCLSS) name the application. The second part of the performance class is the location (e.g., CH - Cherry Hill, New Jersey). The columns that follow give the

*SAS is a registered trademark of SAS Institute Inc. Cary, NC, USA.

total transactions for that performance class followed by the number of transactions whose response fell within the counter boundries. This is followed by the percent this represents within each counter boundry. The last column shows the average response for the performance class. For example, there were 9066 CICS transactions from the Cherry Hill office. Of these 6474 or 71.4% completed in under 1 second, 91.0% completed in under 2 seconds, 95.2% in under 3 seconds and 98.1% in under 5 seconds. The average response time was 1.19 seconds.

VALIDATING THE DATA

For purposes of validating the data, displaying the response time on the user terminal affords the best opportunity for validation. The NLDM response times displayed at the terminal for individual transactions appear to be very close to the perception of the terminal user. For example, a logon is reported by NLDM to take about 15 seconds. Using the second-hand of a watch to verify this, the time is identical. Other transactions are too fast to verify with a watch but appear to be very close to the terminal user's perception of the elapsed time.

Trying to validate the data that is written out to the SMF records turned out to be a difficult task since the data must be compared on an "apples-to-apples" basis at the terminal level. Attempting to keep response time statistics at the terminal level requires a considerable amount of disk space. Also, the data collectors for most applications are not designed for summarizing the data to this level. However, with TSO/MON from Morino Associates, it is possible to collect host response times and sampled network delays for TSO to the terminal level.

Table 2 compares the TSO/MON response time statistics during peak hours (9:00-11:00 and 13:00-16:00) to NLDM's reported statistics during the same time period.

It is interesting to note the similarity, in most cases, between the TSO/MON sampled end-user response time and the NLDM measured end-user response time. This could be considered more a validation of the TSO/MON sampled network delay than of NLDM's measured response time.

Initially, it was expected that the host reported average response time and the NLDM reported average response time for locally attached terminals would be nearly identical. However, as can be observed from Table 2, this is not the case. Investigation has shown that this difference is primarily due to queueing delays within the 3274 control unit. According to studies performed by IBM (4), the control unit delay accounts for between .1 and .3 seconds for a full screen of data. These queueing delays appear to have been reduced on the 3174 control units, however, at the time of this writing, this had not been confirmed.

Remote users can expect further communications delays caused by line speeds, queueing in the FEP, number of drops on the line and other factors.

It should be noted that the largest variances that can occur are in the host reponse times. Depending on the type of transaction, host response times can vary from .2 seconds to 15 seconds or more. Network delays including control unit delays remain relatively constant across all transactions.

USING THE DATA

One of the uses for the data from NLDM is to set and report on end-user response time objectives. List II shows the table of response times compared to objectives (expected response) that we issue on a monthly basis.

This table, along with other important charts and tables are sent out in the form of a monthly report to several key users and managers.

The table shows the past three months' percent less than objective time and average response time for each location by application. Three months of data affords the user a clearer picture of the current month's data. A weekly version of this table is also produced and distributed to key MIS personnel so that any problems that arise can be dealt with as soon as possible.

Issuing a report on remote response times may not answer users questions completely. For example, one of the key top managers who receives this report was curious about the types of responses being received at Los Angeles. To monitor this location, a daily chart was produced (see example - List III) showing a breakdown of the transactions. This raised further questions as to the types of transactions that were greater than 5 seconds. By using the total response time as reported by NLDM and subtracting the average host response times we could determine the average network delay. Knowing this, we used the CICS component of MICS to identify those transactions whose host response time plus network delay were greater than 5 seconds.

Knowing the types of transactions that would cause long responses, the Los Angeles office personnel were instructed to inform the customer that a delay would occur. In some cases the customer was told that he would receive a call back when processing was complete.

In another study, similar charts were generated to prove that multi-dropping 56 Kbps lines would have a negligible impact on response times. This provided a cheaper alternative than adding dedicated lines and postponed the acquisition of an additional 3725.

COSTS

One of the questions that may have to be answered before using NLDM with RTM's is "Do I want to collect response time for all terminals in the network?". Depending on the size of your Network this may be impractical. We chose to select representative control units to be upgraded with RTM's. Another concern is that certain models of the control units (3274's) do not have options for adding an RTM. The cost to add an RTM is as little as $600, but may be considerably more if the control unit requires upgrading to a different model.

CONCLUSION

Using NLDM a measured end-user response can be obtained. Using an extraction tool, this data can be extracted from the SMF record created by this product and can be used to identify problem areas or areas in the network requiring upgrades, confirm or refute end-user response time complaints and to establish and report on end-user response time objectives.

LIST I

The following is a sample member which would be defined within your NCCF parameter library. The definition statements in this member describe measurement parameters used by the RTM. There are two types of statements described in this member, the performance class (PCLASS) and a statement to map the session to the performance class (MAPSESS). Mapping of sessions to a performance class can range from all or a group of terminals as defined by a portion of their VTAM node name to a specific terminal (See PCLASS of TSOLCLT and MAPSESS of MAP2AT below).

ABSTRACT

Seven principles for designing responsive systems are presented. They generalize and formalize the expert knowledge that performance specialists use to build or tune systems. The principles are oriented to large systems of programs in early development -- requirements definition and preliminary design creation. Most software designers can easily understand and use the principles to build better systems. The paper introduces and illustrates the principles, discusses their effective use, and suggests how they can be useful to a performance specialist who already possesses expert knowledge.

1.0 INTRODUCTION

Software Performance Engineering (SPE) calls for building performance into new systems rather than tuning it in after implementation. It prescribes models for predicting software performance and a software engineering methodology for gathering data and interfacing the SPE activities with the software engineering process [SMI81, SMI84]. If you have tried it, you have probably discovered that it is possible to detect performance problems early in the development process while there is still time to correct them. You have probably also found that it is easy to detect performance problems in software designs -- they are "obvious" to performance specialists -- yet it is often necessary to construct performance models to prove it. Even then, designers may require justification of the model assumptions rather than immediately recognize and correct software problems.

In applying SPE to numerous software development projects, we have observed much commonality in the design problems and gained some insight into why they occur. This paper presents some general principles for performance oriented design that most designers can easily understand and use to build better systems. To experienced performance analysts they are not revolutionary new ideas. They are, however, a generalization and abstraction of the "expert knowledge" that performance specialists use in building or tuning systems. They are also an effective way to communicate this knowledge to software architects and designers.

As mentioned, the SPE methodology and models have been around for a while [BOO79, SAN78, SAN79, SHO75, SMI80a, SMI80b]. Similarly, program efficiency guidelines are well known [BEN83, FER78, FER83, KNU68, KNU71, KNU73]. Alternatively, these general principles apply to large ***systems*** of programs in ***early*** life cycle stages, when one is concerned with formulating requirements and design specifications that will lead to ***systems*** with acceptable ***responsiveness***. While many of the fundamental performance concepts are similar, large system design is different. Tuning transforms a program into a more efficient program that performs the same function. The principles address ***what*** functions a system performs as well as ***how*** they are performed. Similarly, responsiveness to users is not necessarily the same as efficient use of computer resources. Note that the principles ***supplement*** the SPE models, they do not replace them.

The next section introduces the seven principles, and Section 3 discusses using them effectively. Then Section 4 suggests how they are useful to a performance specialist who is already familiar with the performance concepts.

2.0 SYNTHESIS PRINCIPLES

These principles have been developed through practical experience with large software systems. On one particular project, severe performance problems were detected during the system integration phase. A thorough performance "tuning" study was conducted that resulted in numerous proposals for improvements. Many were deemed infeasible because of the magnitude of the change at the late development stage. Others were implemented as proposed. Each of the proposed improvements was catalogued and classified by the type of change. The classifications were related to a performance model such as that in the Appendix, and the generalized set of principles was formulated on the basis of the relationship between the changes and the impact on the parameters of the performance models.

The principles apply to software systems, large or small, executing on a spectrum of computer systems: microcomputers, large mainframe computers, distributed systems, and MIMD computers.[1] They are most effective for very large software systems with high processing demands.

The following sections present the seven general principles for the synthesis of responsive software systems: fixing, locality design, processing versus frequency tradeoff, shared resources, parallel processing, centering, and instrumenting. Each principle is defined and explained using simple examples. A hypothetical automated teller machine (ATM) example illustrates many of the principles. Examples are provided for both system requirements and design tradeoffs.

2.1 FIXING POINT PRINCIPLE

Fixing is the mapping of an action or function desired to the instructions that accomplish the action. It is also the mapping of information required to the data used to produce it. The fixing "point" is a point in time. The latest fixing point is during execution immediately before the action or information is required. Fixing could be done at several earlier points: earlier in the execution, at program initiation time, at compilation time, or external to the software system.

> ***Fixing Point Principle: for responsiveness, fixing should be done at the earliest feasible point in time such that retaining the fixing information is cost-effective.***

This is often viewed as a resource usage versus flexibility trade-off. Early fixing leads to far more responsive systems while later fixing is more flexible and general. Late fixing provides flexibility in two ways: through automatic linking of actions (or information) to the most recent version of the corresponding instructions (or data), and by imposing fewer constraints on which actions (or information) can be executed (or accessed). Late fixing of actions affects responsiveness since the code for fixing the actions to the instructions must be executed every time the actions are requested. Similarly, late fixing of information to data requires executing the fixing code every time the information is accessed. The fixing code is executed unnecessarily when no changes have occurred since the last use and when common, predictable actions and information are used.

1. When the processors have conventional von Neuman architectures. This excludes pipelined processors, systolic arrays, and other special purpose architectures. Such computer systems may have additional performance-determining factors not addressed here.

Often, software is more general than required. When users are uncertain how they will use the system, they request generality. However, it is better to consider early its effect on performance, to invest the time to study how systems will be used, and to include generality only where it is really needed. As a compromise, early fixing should be done for the functions that are used most frequently, and generality included only for the less frequent functions.

It is cost-effective to retain the fixing information when the cost of retaining it is less than the cost of fixing multiplied by the probability that re-fixing is unnecessary. Jobs or transactions will be more responsive when customized interfaces are designed with early fixing for common predictable actions and information, and when baselined versions of information are changed infrequently and are fixed early. For flexibility, special interfaces can be provided and used only when needed for uncommon actions, for information infrequently accessed, and for re-fixing to more recent versions as required.

An example of fixing requirements is choosing the interface for DBMS information selection. Runtime fixing is done when general ad-hoc queries against the information are allowed, and the query is parsed and satisfied at runtime. Alternatively, the information can be fixed earlier, at compile time, with managed queries: pre-defining the information that is to be quickly accessible and building a menu with only those items. The data is still selected at run time, but the code to retrieve it is fixed at compile time.

Note that binding is a subset of fixing. An example of fixing that is not binding is determining when data in files or internal tables should be sorted. Files or tables kept in the desired order, with all additions preserving the order, are fixed early. Late fixing applies to ordering them when needed. (Some experts would consider this an example of "extended binding." Unfortunately, many subconsciously view binding in a limited context, so the term *fixing* is used to encourage broader interpretation.)

2.2 LOCALITY DESIGN PRINCIPLE

Locality refers to the closeness of the mapping of logical tasks and resources to physical resources. According to Webster, ***close*** means "being near in **time, space, effect** (that is, purpose or intent), or **degree** (that is, intensity or extent)."

The dictionary specification for close mapping then leads to four types of locality design for performance engineering. They are illustrated in the following example. Consider the logical task to sort a list of integers. *Temporal locality* of the mapping of this logical task to the physical resources is better if the integers are all mapped at the same time to the physical processor that sorts rather than one at a time (with a large interval of time between each). Similarly, *spatial locality* is better if the task is in a location that is near the physical resource, such as in memory that is directly accessible by (local to) the processor on which it will execute, rather than located on a disk drive attached to a different machine. The task could be mapped to different types of physical processors; consider the choice of mapping to a general purpose CPU or mapping to a special purpose chip designed specifically to sort lists of integers. *Effectual locality* is better for the special purpose processor since its purpose matches the task more closely than the general purpose CPU. *Degree locality* refers to the extent of the task, as in the length of the list of integers as compared to the size of the processors (e.g., speed, memory, size, etc.).

The locality design principle can thus be stated as follows:

> ***Locality Design Principle: Systems should be designed to have a close mapping of logical tasks and resources to physical resources.***

Spatial locality is in menu networks that cluster related activities into a single menu and changes menus when user activity changes. For temporal locality, those activities that are requested most frequently should be in the first menu seen by the user; infrequent activities should be seen much later. (Since they are clustered into the same menu, they also have good spatial locality; temporal locality refers to *when* they appear in the sequence of menus.) Effectual locality is found in most ATM's: they use a special purpose automated teller machine that has a user interface customized to the ATM application, rather than a general purpose terminal console. Degree locality matches the size of the ATM application to the machine. A microprocessor is sufficient, a supercomputer is not needed.

2.3 PROCESSING VERSUS FREQUENCY TRADEOFF PRINCIPLE

This principle addresses the amount of work done for each processing request, and its impact on the number of requests made. The "tradeoff" concerns the cases when more work per request reduces the number of requests made, and vice versa. The principle is as follows:

> ***Processing versus Frequency Tradeoff Principle: Minimize the processing times frequency product.***

A requirement tradeoff for the ATM example is determining whether multiple transactions per ATM session are to be allowed. The prompt for continuing a session requires some additional processing time, but the total number of sessions may be less than when a separate session is required for each transaction.

Another example is in displaying results of a database query when multiple data items are selected. Either all results can be displayed with a GETALL, or the first item can be displayed with a GETFIRST and each additional one with a GETNEXT. If users frequently wish to display all results, then the GETALL command may be desired for convenience. The principle can then be applied to the design. A design with a direct GETALL has a high bandwidth interface to the database; a design with an intermediate level of abstraction intercepts the user's GETALL request, issues multiple calls to the database (the GETFIRST and multiple GETNEXT's), accumulates the results, and transmits all back to the user at once.

There is not always a tradeoff in the two factors. For example, for file I/O one can retrieve one byte of information at the same relative cost as 20 bytes of information, because the processing time is dominated by the I/O operation. Therefore, if most of the time the additional information is eventually required, there will be essentially no change in processing time *and* the number of requests will be reduced. Thus there is no processing time penalty for reducing the number of requests.

There are three special cases of this principle that commonly occur in large software systems. The special cases relate more directly to decisions made during software development and should provide a better understanding of the general principle. In the following paragraphs each of the special cases is defined and an example is included. The first two cases illustrate increasing processing and reducing frequency. The third illustrates decreasing processing.

The first is the "family plan." The analogy is providing service for the first family member for full fee, and thereafter providing services for all additional family members at the same time at a negligible additional fee. An application is an "access list" strategy for maintaining a list of resources that a user has permission to access with the types of access allowed for each. A "security guard" within an operating system can obtain the access rights for all resources of a particular user at a negligible additional cost over obtaining the access rights for one resource. The family plan applies when multiple requests for resources from the same user are likely to occur within a short period of time.

A variation is the "maximum use of overhead costs." With it, service requests are grouped into "batches" to process multiple requests for each overhead penalty. An application is a hypothetical distributed computing environment where many users share a local machine for editing, compiling, and executing minor tests. Major tests are submitted to a remote machine. Submission requires the execution of "overhead" software to establish the communication link, to transmit the request, and to receive the reply. The "maximum use of overhead costs" implies that requests for major tests should be collected (delayed) and periodically transmitted to the remote machine. It is applicable when the batching delay is small compared to the duration of the major test, and it is likely that multiple requests will be made during that delay period.

The third special case is the "expensive processing reduction." With it, expensive processing is done only when it is necessary. An application is a database with a high degree of locality of access to the data. With "expensive processing reduction," when information is requested, the software first checks to see if it has been recently retrieved. It is applicable when it is highly probable that the check will be successful, and the processing time is substantial. Another example is in reservation systems; when a customer calls to check previously made airline or car rental reservations, a short record that contains frequently accessed information is often fetched first. Processing takes longer for less frequent requests such as reserving a special meal.

2.4 SHARED RESOURCE PRINCIPLE

Computer system resources are limited and must be shared. To share, either multiple processes can use the resource at the same time, or they can take turns, each process using the resource one at a time (multiplexing). The management of shared resources affects the software in two ways: the additional processing overhead for scheduling the resource, and the possible additional time for waiting to gain access to the resource. The general principle is as follows:

> ***Shared Resource Principle: resources should be shared when possible. When exclusive access is needed, the sum of the holding time and the scheduling time should be minimized.***

By sharing resources (rather than taking turns), the overhead for scheduling is minimized and there is minimal wait to gain access (there may be a wait if another process already has exclusive access even though the requestor is willing to share).

Decreasing the sum of the holding time and the scheduling time of multiplexed resources decreases the *average* wait time to gain access to the resource.[2] There are four ways to minimize the holding time:

1. *Minimize the processing time (using the other principles)*
2. *Hold only while needed*
3. *Request smaller resource units*
4. *Fragment the resource requests*

The first decreases the holding time by doing less work while the resource is held. The second says that a multiplexed resource should be requested just before it is used and released immediately afterwards. The third, requesting smaller resource units, means that less of the resource is held. The fourth, fragmenting requests, means partitioning one request that requires a long holding time into shorter requests, each of which requires a shorter holding time.

Minimizing the holding time of a multiplexed resource may increase scheduling time. The scheduling of service requests requires more processing for smaller resource units; and fragmenting requests into multiple shorter requests introduces more requests for scheduling service. ***There will be a net improvement only when the additional processing is less than the expected wait time using the larger units or longer requests.***

In the ATM example, when a function is requested that changes the account master file, such as a withdrawal, only one request can be allowed to modify the file at a time to ensure file integrity. This can be implemented by allowing only one ATM to be active at a time. That is, the central computer completes one ATM transaction before beginning the next. An alternative is to allow multiple ATM's to be active concurrently and to add additional processing to request exclusive access to the account master file only during the critical time when the balance is being changed. The preferable alternative and the magnitude of the savings depend on the frequency of requests that require exclusive access to the master file.

The above was an example of locking only when needed. Smaller resource units implies locking at an account level rather than for the entire database. Locking for the entire database requires only one lock, while locking for accounts requires many. Therefore, the scheduling time to search through the list of locked accounts is greater than the time to check the flag for the entire database. Of course, the space requirements are greater as well.

There are also several choices for the degree of fragmentation requests. The software could lock for the first request that requires a change to the database and hold it until the customer completes the ATM session. Alternatively, it could lock and free the database immediately before and after any change.

2.5 PARALLEL PROCESSING PRINCIPLE

Processing time can sometimes be reduced by partitioning a process into multiple concurrent processes. The concurrency can either be real concurrency where the processes execute at the same time on different processors, or it can be apparent concurrency where the processes are multiplexed on a single processor. For real concurrency, the processing time is reduced by an amount proportional to the number of processors. Apparent concurrency is more complicated. Although some of the processing may be overlapped (e.g., the CPU, memory, or files), additional wait time may be introduced. Additional overhead processing may also be required to manage the communication and coordination between concurrent processes.

The principle is as follows:

> ***Parallel Processing Principle: parallel processing should be exploited (only) when the processing speedup offsets the communication overhead and the resource contention delays.***

In the ATM example, the microcomputer at the ATM site allows for parallel processing. The following is one such strategy:

- The ATM micro computer requests the account information and the authorization code, and sends it to the central computer.
- While the central computer is verifying the account number and authorization code, the ATM microcomputer obtains the transaction selection and information required.
- It formats and sends the transaction information to the central computer. While the transaction is being processed at the central site, the ATM begins printing the receipt for the customer.
- While waiting for the response, the ATM micro asks if another transaction is desired, and if so, begins processing it.

2. The shared resource principle is a synergistic principle; it improves the average waiting time for all processes, rather than improving a process's own responsiveness. See Appendix for further information.

This processing strategy is complex since many special cases must be handled. For example, the customer might first request the account balance; while that transaction is being processed by the central computer, the customer requests a withdrawal. When the account balance arrives from the central computer, the balance is insufficient to cover the withdrawal. This does not introduce a processing time delay, but it complicates the number of situations that the microcomputer software must consider.

In general, the benefits derived through apparent concurrency are not significant compared to those achievable using the other principles. It has the further disadvantage of adding complexity to the software system. Real concurrency will be effective if the processing time reduction is much greater than the additional overhead for communication and coordination of the concurrent processes. The performance improvement must also be weighed against the cost of the additional processing power and the cost of more complex software, to determine whether it will be effective.

2.6 CENTERING PRINCIPLE

The five previous principles provide guidance for the synthesis of software requirements and designs. Their application improves the performance of the part of the system to which they are applied. This principle is different in that it addresses leveraging the application of the principles by focusing attention on those portions of a large software system that have the greatest impact on its responsiveness. It is based on the folkloric "80-20 rule" for the execution of code within programs. A generalized version is: a subset ($\leq$ 20%) of the *system functions* that are available will be requested by the system users most ($\geq$ 80%) of the time. These frequently requested functions are called the dominant workload functions (they also cause a subset ($\leq$ 20%) of the *programs or modules* in the software system to be executed most ($\geq$ 80%) of the time, and the code within modules, etc.) Performance enhancements made to these key areas of the software system thus greatly affect the overall responsiveness of the system.

The principle is as follows:

> ***Centering principle: identify the dominant workload functions and minimize their processing.***

That is, create special execution paths for the dominant workload functions that are customized and trimmed to include only processing that *must* be done while the user waits. The principles in Sections 2.1 through 2.5 are applied to the special paths to minimize their processing. Separate transactions should be constructed for the workload functions that are requested less frequently.

Most automated teller machines apply the centering principle to system requirements by including a "quick withdrawal" transaction that reduces processing by eliminating prompts and processing for account type, amount, and additional transactions; and (on some ATM's) by omitting the new account balance from the receipt. They also apply it to the system design by customizing the access methods for the small percentage of customers who are likely to use ATM's.

Note that centering emphasizes optimizing frequent requests. Although it is not explicit, this implies that is generally not profitable to worry about the responsiveness of functions that are infrequently used; the modifications may lead to negligible improvements, or even to degradations. The exceptions are for important, but infrequent, functions or for functions that have large processing times.

The centering principle applies to all systems, but *what* one centers on may depend on the performance goal or the type of system. Thus far, the discussion has implicitly addressed application software systems that support online interactive users where the performance goal is responsiveness to users. When system throughput (number of responses per unit time) is a performance goal, or general purpose software systems do not have a dominant workload, centering is on those components with the largest cumulative space - time product across the specified usage scenarios. Note that *most* general purpose systems (e.g., database systems, operating systems, or other commercial products) have dominant workloads. The developers may not know what they are, but they can be identified and it is important to do so. If one instead focuses only on the components with a large cumulative space - time product, improvements can be made by reducing their time, but other opportunities to shorten path lengths by eliminating general processing steps not applicable to the dominant workload may not be found.

Early in the life cycle, centering focuses on the functions frequently requested by users. Later, during implementation, the centering principle also addresses software components with large resource demands, the "major consumers," even though they may not be executed frequently. Because the major consumers hold resources, they may cause excessive delays to the dominant functions. While they can be identified earlier, they are typically less important than the dominant functions. They are addressed later, but do not drive the design earlier as do the frequent functions.

There is an additional difference in the early and late life cycle centering considerations: the effect of the improvements. Early life cycle centering focuses on the functions frequently requested by the users. We assume that reducing the processing time for these requests does not affect the number of times they are requested. Later in the life cycle we also address the major consumers of resources. When their processing time is reduced, the components that fall in the set of major consumers of resources may change. Thus, reducing the resource requirements of the major consumers could be an endless process, since there will always be major consumers of each resource. It is not endless because we focus on achieving the performance goal, not on minimizing resource usage.

2.7 INSTRUMENTING PRINCIPLE

Instrumenting software means inserting code at key probe points to enable the measurement of pertinent execution characteristics. The principle is:

> ***Instrumenting Principle: Systems should be instrumented to enable measurement and analysis of workload scenarios, resource requirements, and performance goal assessments.***

This principle does not in itself improve performance, but is essential to **controlling** performance. It has its foundations in engineering, particularly process control engineering. Their rule of thumb is "if you can't measure it, you can't control it."[3]

Probes should be inserted to collect the number of times workload scenarios are executed, how often software components are executed, and their resource requirements. Performance engineering also calls for identifying the system functions that are used, and the information that is accessed. Since the functions are fixed to software components and information is fixed to data that is accessed, instrumentation is needed to identify and measure the relationships. This discussion focuses on instrumentation for performance engineering; data should also be collected to control other aspects of software quality.

For the ATM example, instrumentation is needed to enable collection of:

- Number of times each ATM site is used, customer arrival rates, and the peak load characteristics
- Number of times each ATM function is selected, and the number of times errors are made

3. I have always believed that instrumenting software is important to performance. Nevertheless, I omitted instrumenting in my original set of principles since it does not directly improve performance. Kopetz presented a paper on principles for designing fault tolerant real-time process control systems, and included an instrumenting principle [KOP86]. He persuaded me that it is vital and should be adopted, even though it does not directly improve performance.

- Number of times each software component is executed
- For each component: the amount of CPU time, number of I/O's, memory, procedure calls, etc.
- The withdrawal amounts, the accounts accessed, the number of transactions local to the bank versus those that access a national network, and the number of transactions in a session
- The total time for: the user to respond to requests for information, the completion of a transaction, the completion of a session

The above is a partial list of the data of interest. Collection of this data should be considered when the system requirements and design are conceived; it is much more difficult to obtain later. This is because of limitations in instrumenting technology - most tools collect system level data such as program execution time rather than functional data such as end to end response time (e.g., ATM transaction or session time). Functional data currently requires programmers to insert code to call system timing routines and write the key events and pertinent data to files for later analysis. Additional tools and techniques are needed to automate the data collection and facilitate the data analysis.

2.8 SUMMARY

In this section, the principles for synthesis of responsive software systems were introduced and illustrated with simple examples. Most of them involve tradeoffs. A quantitative analysis of the performance effect of the fixing point, processing versus frequency tradeoff, and centering principles is in [SMI86b]. While they can be evaluated with simple back-of-the-envelope calculations, the others require more sophisticated performance models. Since the performance engineering methodology in [SMI81] incorporates the modeling activity into the software design process, it is easy to use the models to quantify the tradeoffs. Many performance analysts have the necessary modeling skills, and numerous support tools are available.

3.0 STRATEGY FOR EFFECTIVE OPTIMIZATION

The general principles are necessary for developing systems with good performance characteristics, that is, for "doing it right the first time," but they are not sufficient. There are four factors that determine their effectiveness; the principles must be:

1. *Applied to appropriate software components*
2. *Necessary*
3. *Lead to global improvement*
4. *Cost-effective*

Each of these is explained in the following paragraphs.

The principles must be applied to the components that are critical to performance. Identifying them at design time can be difficult; and intuition can be misleading. Some designers mistake the components that are most difficult to design and implement for the critical components; whereas, the critical components are generally those most frequently executed.

For example, network security management is difficult to design because many complex situations must be handled. Security may require a fair amount of execution time; however, other network software components, such as the communication protocol routines, are generally more frequent. Security management *may be* critical to performance, modeling determines its impact.

The second effectiveness factor is applying the optimization efforts to software components only when *necessary*. Usually, it is unnecessary to overachieve a performance goal; therefore, if the performance goal can be easily attained, it is not effective to devote valuable development time to extensive performance enhancements. Similarly, it is not effective to expend much effort optimizing components of the software system that have little impact on overall performance.

Another aspect of necessary optimizations is distinguishing software requirements that are necessary from those that are both unnecessary and adversely affect responsiveness. Sometimes these "artificial" requirements are introduced at design time with the intent to improve performance. An example is (an extra) requirement for a component that produces a list of items: that the list be in sorted order. The order requirement may be artificial, the intent being to reduce subsequent search time. Performance models show whether the sort improves overall responsiveness. A straightforward approach (eliminating the sort) may not degrade responsiveness, and will result in less code to maintain.

The third effectiveness factor says that optimization techniques should result in *global improvements* to the software performance. This is most important in detailed design and coding stages, when many people are involved in development. Optimizations made in one part of the software system must be consistent with those made in other areas. Performance models quantify the overall effects.

The last of the four factors is that the performance improvement must be *cost-effective*. The time to implement the optimizations must be weighed against expected savings. It may be extremely difficult to achieve a specified performance goal for a large software system. Achieving the goal may be possible only at great costs in personnel time and in elapsed time to implement the system. It is important to estimate the cost of achieving the performance goal and insure that it is justified. It is often possible to negotiate for more reasonable performance goals before expending excessive efforts to achieve unrealistic ones.

4.0 RELEVANCE TO PERFORMANCE SPECIALISTS

These principles formally state concepts that are already familiar to experts in performance oriented design, so why is this paper appropriate for CMG audiences? Suggestions on how to use these principles to improve software performance in your organization follow.

The first and easiest use is to incorporate the principles into software performance engineering studies. SPE calls for systematically assessing performance trade-offs throughout development. The principles guide the identification of improvements and help explain the rationale for the changes to designers. The instrumenting principle suggests working with designers to help them identify what should be measured, and the best way to do so. It also suggests developing standard software for measurement data analysis and reporting that can be used by all new software systems.

There are obvious differences in personal aptitudes for performance oriented design. While some designers will never be interested in performance, many others are interested in and willing to create high performance systems, but they lack the necessary training and experience. These people quickly grasp the principles, especially when they see examples relevant to their applications. Another use for the principles is to educate designers. Publicize references and suggested reading material in internal newsletters. Suggest LAM84, SMI86a, SMI87, or KOP86 (for real-time process control systems). Suggest commercial seminars on software performance engineering to your designers, or develop your own. Develop some applications of the principles using your systems as examples. Many important design issues are discussed in SMI87, such as communication, human interface design, data organization, and information hiding. Customize those examples to your environment and educate your designers.

Another way to use the principles is to create software tools to help designers evaluate trade-offs. Figure 4.1 shows a hypothetical tool to evaluate the effect of centering by creating special processing paths for dominant workload functions. It asks for estimates of processing and frequency, and produces the resulting average processing time and time savings. Your tools could also interface with software model analysis tools to calculate the processing time, and commercial system modeling tools to solve for response times. The formulas that provide these results are in [SMI86b].

You could also produce some "engineering reference tables" using the formulas in [SMI86b]. Figure 4.2 shows a table for evaluating the effect of centering. For example, if the general path takes 5 seconds, a special path could be created that takes 1 second, and 9 out of every 10 requests are for the special path, a designer could compare the average processing time with the special path (1.4 seconds) to the average time without it (5 seconds). You can generate a handbook of tables like this for parameter values that are common in your environment and for the other general principles. You could also estimate the effect on response time (rather than on processing time) using estimates of queueing delays for your environment.

Another use for the principles that appears to be viable in the near future is an expert system for performance oriented design. By formalizing the expert knowledge, we are one step closer to automating the detection and correction of performance problems.

Figure 4.1
Hypothetical Trade-off Analysis Tool

Input:	
Name of special function	*quick withdrawal*
Additional processing to identify it (seconds)	*0*
Processing for general path (seconds)	*20.6*
Processing for (separate) function (seconds)	*6.8*
Ratio of special to total functions	*9/10*
Report:	
Processing time - general path (seconds)	*20.6*
Processing time - special function (seconds)	*6.8*
Average processing time (seconds)	*8.18*
Average processing time savings (seconds)	*12.42*

Figure 4.2
Engineering Reference Table: Centering

Average Processing Time

Probability of special path = .09
Additional processing to identify special path = 0

Processing for special path:

	0.1	0.5	1	1.5	2	2.5	3	3.5	4
Processing for general path:									
1	0.19	0.55	1	1.45	1.9	2.35	2.8	3.25	3.7

Appendix
Basis for the Principles

The computer system on which the software executes can be viewed as an abstract model as in Figure A.1. Figure A.1a shows several types of jobs (A,B,C,...) arriving for service, possibly waiting in a queue for their turn for service, then leaving upon completion. Figure A.1b shows an expanded model that identifies computer system resources that each of the jobs may use while being served. It is well known that the performance of such a system depends on the following parameters of the model [LAZ84, SAU81]:

- the arrival rate of each type of job
- the computer system resource requirements of each type of job
- the contention delays that result from the interaction with other jobs in the system
- the scheduling policies used to determine which waiting job next obtains the needed computer system resource

The seven principles improve performance by favorably affecting the corresponding system performance parameter. Table A.1 summarizes the correspondence:

Table A.1

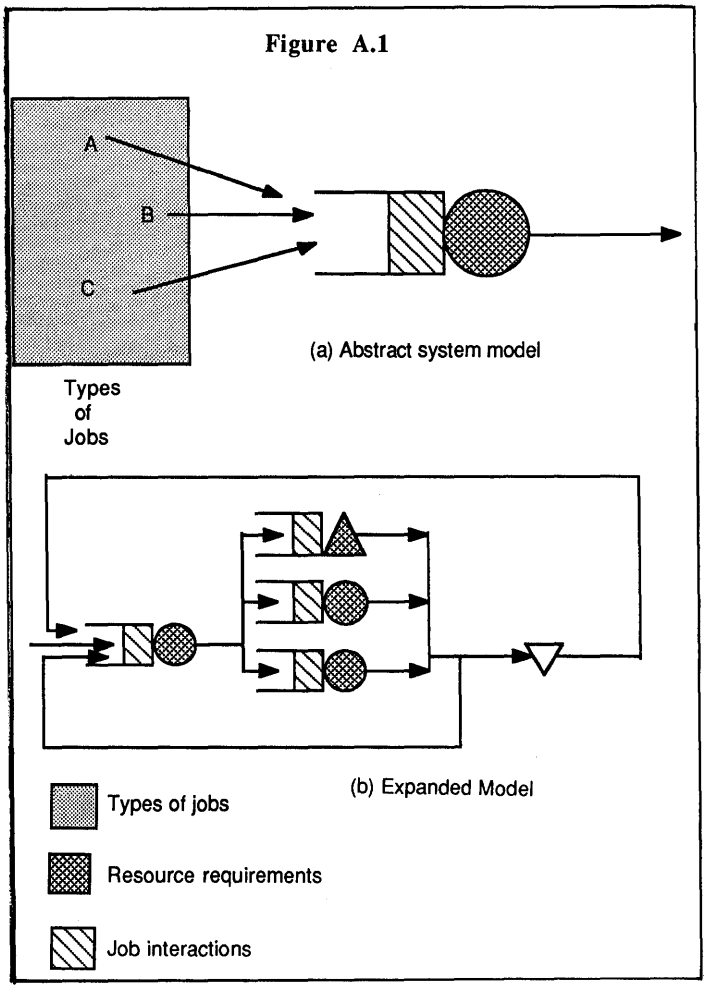
System Parameter	Performance Principle	Type
Resource Requirements	Fixing Point	Independent
	Locality Design	Independent
	Processing vs. Frequency Tradeoff	Independent
Job Interactions	Locality Design	Synergistic
	Shared Resources	Synergistic
	Parallel Processing	Synergistic
Types of jobs	Centering	Independent
Scheduling	—	—
—	Instrumenting	Control

The fixing point principle concentrates on when and how often processing occurs. Locality design pertains to effective use of resources. Processing versus frequency tradeoff affects the number of requests for resources and the amount requested. Shared time interval. The extent of parallelism and the competition for resources among the parallel tasks is affected by the parallel processing principle. Centering focuses on the jobs that are key to the responsiveness of the system. The scheduling of jobs is not addressed because it is generally a service provided by the computer system, and not frequently a decision that must be made in the early development stages of new software systems. If scheduling is addressed, it is usually only after implementation when job priorities are manipulated. The instrumenting principle does not directly influence the performance-determining factors. Instead, it addresses ***controlling*** the other factors.

There are three types of principles shown in the table, independent, synergistic and control. Independent principles improve the responsivenss of the "job" to which they are applied by improving its own performance parameters (e.g., reducing its resource requirements). Thus the improvement is *independent* of the characteristics of other types of jobs. The synergistic principles, on the other hand, improve the overall responsiveness through *cooperation*: they can reduce the average time waiting for resources if the competing jobs abide by the recommended principle. The locality design principle is both independent and synergistic, because it can improve a job's own responsiveness as well as benefit competing jobs. As mentioned, the instrumenting principle is for control; it has no direct effect on performance, but is vital to managing it.

Most of the principles require a tradeoff decision. The performance of the various alternatives may not be obvious, particularly for the synergistic principles, since it is affected by many interrelated factors. A previous paper provided quantitative improvement formulas for the independent principles [SMI86b]. Performance models similar to Figure A.1 can aid in the decision making for the synergistic principles [SMI80a, SMI80b]. Because of the interaction, though, the definition of some of the principles may seem ambiguous. In practice, the performance engineering models (similar to that in Figure A.1) resolve the ambiguities.

Figure A.1



THE SYSTEM PERFORMANCE CYCLE: A METHODOLOGY FOR ARCHITECTING PRODUCT PERFORMANCE

Doug McBride
Hewlett-Packard Company
Performance Technology Center

ABSTRACT

Rather than wait until a computer software product has been designed and implemented to determine what its performance capabilities are, it is suggested that performance criteria be specified during the product investigation and design phases in order to ensure that acceptable levels of performance are realized at product completion. The methodology used to ensure performance goals are met, although straightforward, is not necessarily intuitive. This paper outlines the process known as "The System Performance Cycle", a set of guidelines used at Hewlett-Packard for the purpose of directing product teams toward producing software that performs when functionally complete, as opposed to having to go back and "tune" the product after performance shortcomings have been detected during post-release usage.

INTRODUCTION

Throughout the first three decades of the computer industry's existence, users of computer systems typically measured the efficacy of their machines by reliability (translated as "up time "), throughput (amount of "useful work" performed per unit time), and relative functionality (how "well" the system did the required work). These were the days of predominately batch processing where the end user had little or no contact with the system other than the submission of a work request and the receipt of the corresponding output within a certain period of time (usually the next day or beyond). The metrics used to define system performance were mainly batch, and the time frame was one of hours, or in the extreme,days.

Over the years advances in semiconductor technology made possible smaller, less expensive, and faster computer systems. These systems inspired a move toward "online" or "transaction" based processing where the end user interacted directly with the machine through some form of dialogue at a keyboard/display device. With this form of man machine interface came a new perspective on system performance; the emphasis became one of "how quickly" rather than "how much" (of course we know there is a relationship here, but the priority was on waiting the minimum amount of time for service by the system).

During the evolution of the online system concept, many installations experienced performance problems (poor response times) as the demand for system services grew and the complexity of the applications run on the machine increased. Initially, the solution to these performance problems was monolithic; buy a larger (read "more powerful") machine of the same family from your computer vendor and system performance improved commensurately. This worked early on due to most organization's adherence to the centralized data processing center concept. As technology made distributed processing via the smaller "work group" machine possible however, the performance-to-cost ratio could not be improved to the point of solving performance problems economically with hardware, especially in a machine family with a broad range of hardware capabilities.

At Hewlett Packard (HP), this concept became clear as the HP3000 family of computer systems grew in two directions; initially towards the "supermini" class of machine used to replace smaller "mainframe" type machines in transaction processing environments, and later the family grew into the smaller (10 - 30 user) "work group" class of machine to support OA and small business applications. Many of the software applications sold by HP and/or third party vendors ran fine on the large machine, but consumed inordinate resources on the small machines causing performance degradation severe enough to sometimes cause customers to look elsewhere for solutions.

A methodology needed to be put in place which would ensure software products would meet certain performance criteria prior to being released to the HP customer base. The methodology was created and refined by a group at HP Laboratories during the early days of research into the Hewlett Packard Precision Architecture to be used in the development of software systems for the new family of HP computer systems. These techniques have also been applied to the development of software for current systems as well as reworking existing software where performance is a problem.

Collectively, this set of procedures is referred to as the System Performance Cycle (SPC). The SPC has proven effective in architecting performance within the design of a software product primarily due to the inclusion of performance factors into all phases of the software life cycle from product specification through maintenance procedures after release. The remainder of this paper is intended to give an overview of the principal parts of the SPC as it is used at HP, as well as how it can be used in any organization to provide similar results.

ESTABLISHING GLOBAL PERFORMANCE GOALS

In studying how software was designed at HP, it was noted that performance was not an explicit line item at any level in the software lifecycle methodology. Functionality is stressed along with a high level of quality with emphasis placed upon what the product will do and how it will react under all circumstances. It is always "implied" that when the product is actually implemented, those who actually write the software will use all the resources at their disposal to ensure system resources are used efficiently and their subsystems will

perform "adequately" when actually used.

Actual experiences have shown that products designed without taking into consideration performance factors, or the interaction of the product with other products running on the same system, typically produce systems with unknown performance characteristics. Unless available system resources are plentiful or the demand placed upon the system is minimal, the interaction of the new product with others alter the overall characteristics of the system in question to the extent that predictable system performance is almost impossible.

In almost all cases, the acknowledgment of this phenomenon comes after product testing/implementation has begun. If the problem is severe enough, it becomes necessary to step back and examine what can be done to "tune" the product to maximize performance and minimize inefficient interaction with other subsystems. If testing techniques don't expose the performance problem during the QA phase, it is possible that the product could be released to customers with the performance quandary showing up at the user's site. In any case, this additional tuning activity is rarely accounted for in project schedules, causing schedule slippage and additional expense which reduce the overall effectiveness of the product to the company. In more extreme cases, poor product performance or severe system degradation can make the product a "non-product" in the user's eyes, causing a major redesign and rewrite in order to make the product viable in the selected marketplace.

The obvious solution to this problem is to include in the product design and specification phase a statement of the overall performance goals the product is expected to meet, along with a statement of system impact to facilitate the prediction of product resource demands on system-wide performance. The target customer (user) of the product should be solicited heavily during this stage to contribute to the overall (global) performance goals of the product, as the product would probably not be created if it were not for the needs of the users (let's face it - its their perception of the usefulness of the product which will determine the overall level of product success). From the description of required performance should come two very specific pieces of information which will be used repeatedly during the design and implementation of the product.

The first item of information (as previously mentioned) is a statement of overall product performance, stated in measurable, quantifiable terms. The customer may state their performance requirements in a somewhat inexact fashion, due to their unfamiliarity with data processing systems and terms. However, it is the responsibility of the design team to restate the performance goals in terms which will be useful parameters as the design phase progresses. This usually involves selecting metrics which are well defined, unambiguous, and above all, measurable.

Typically at HP we use Response Time and Throughput for these measures of product performance. The particular characteristics of the product under development will dictate the context in which these metrics are applied, as well as the definition of the transaction element which will determine how throughput is measured and evaluated. The definition of these terms may vary somewhat from installation to installation, but the importance is not in the precise definition (although the term should be defined for a particular instance), but in the consistency of application of the definition by all involved in the design and implementation of the product. The statement of overall product performance must also be qualified as to the environment under which the product will be tested for compliance to the goals.

The second item of information to be garnered from the global performance statement is a general measure of system resource consumption. Since performance is directly related to system resource availability, the behavior of the entire system environment can be estimated by:

- Understanding and quantifying the total amount of system resources.
- Understanding and quantifying the amount of those resources currently being consumed by existing applications and subsystems.
- Quantifying the additional demand which will be placed upon the system with the implementation of the new product currently under consideration.

This information is key to determining if the system under consideration for implementation of the application is suitable, or if additional resources are needed to successfully run the new product and cause a minimal impact on the operation of the other products and the overall perceived system performance parameters.

Given this data, a key decision point is reached prior to starting the implementation of the product; Can the product's global performance goals be met and still maintain acceptable overall system response? This decision can now be made long before a significant investment of resources has taken place, with commensurate savings if the decision must be made to alter the product strategy including the availability of certain system resources in order to meet product performance goals.

The points worth noting about this portion of the SPC can be summarized:

- It establishes and formalizes the user's expectations of the product's performance prior to detail product design and implementation.
- It causes the design team to take a much closer look at factors which will affect not only the performance of the new product, but the overall effect the product will have on the target system when implemented.
- By focusing on performance before the product is implemented, the resources necessary to support the performance effort are known beforehand, allowing better control of project resources and avoiding the situation whereby significant rework-

ing of the product becomes necessary due to lack of performance and/or excessive system resource consumption.

PRODUCT DECOMPOSITION

The next major step in architecting product performance comes during detail product design. The term "Product Decomposition" is derived from the exercise of determining functional modules within the product which can be measured more easily than the entire product, and will provide insight into where within the product potential performance bottlenecks may be occurring. Additionally, much like in structured design and programming, these modules are basically self-contained from a functionality standpoint and interface to the rest of the product through well-defined and documented input and output paths.

There are several reasons for the decomposition of the product to aid in performance analysis:

- The overall performance of the product can be stated in terms of its components, thereby allowing a more detailed examination of the factors that are affecting the observed product performance during development and testing.

- If a performance problem is detected in a specific module, the effort necessary to isolate it in a smaller module is less than in a larger unit of code.

- Individual modules can be assigned performance goals much like the overall product, allowing for easier modeling and tracking as design tradeoffs become necessary and as the product matures.

- If the product is modeled and formally tracked for compliance to predefined performance goals, the decomposition usually is performed at the level of granularity used for those functions.

Component-level performance goals are initially based upon the design team's estimates of how long the "path length" will be within a specific module (basically, how long the module will typically take to execute), and the time spent in any hardware or software locks and/or latches situated in the execution path. The preliminary figures are based upon either experience, measuring existing code which is similar in function to that which is to be implemented, or simple test routines coded and measured in order to get preliminary numbers to assign to a component.

A simple "paper model" is then created (although a spreadsheet is much faster) which predicts the overall product performance based upon the aggregate observed (estimated) performance of each of the components and their overall level of interaction. Depending upon the initial results of this predictive model, certain modules may require a revision of their individual estimates (based upon further investigation into the reality of achieving the revised performance goal). This process usually alerts the designers to areas of "sensitivity" which may dictate further decomposition or strict observation during the implementation phase of the product (especially if the initial indicators from the paper model show a large disparity from the global goals defined for the product).

The decomposition process becomes then an exercise which provides two major benefits in the design cycle:

- It identifies functional units within the overall product which provide key indicators of overall product performance and whose aggregate performance approximates the expected performance of the product, hence making them likely candidates for instrumentation and measurement.

- By explicitly stating the expected performance goals of each component in terms of "path length" (time in module) as well as time in locks and/or latches, summing the times and verifying a "close" approximation of overall product performance, an important check point is established prior to detail design and implementation which can focus additional resources on investigating potential performance bottlenecks.

MODELING THE PRODUCT

Once the product has been adequately decomposed into a group of functional components whose behavior on an individual basis is clearly understood, a more detailed model can be created to aid in design tradeoff and predictive analysis during product design and implementation. But - before going any farther on the subject - a gentle discussion on the "mystique" of modeling.

Just the mention of the term "modeling" turns a lot of people off. Modeling typically conjures up pictures of a PhD in Mathematics in front of a large chalk board busily writing with one hand and erasing with the other, all material being totally unintelligible to the average mortal. This is just about as true a picture as the old stereotype of data processing professionals wearing long white lab coats, carrying clipboards and wearing black, hornrim glasses. This is not to say it can't be (and sometimes is) that way, but the typical modeling effort does not have to be an exercise in post-graduate math or astrology (although the latter may help in some cases).

As mentioned in the previous section, a simple "paper model" or spreadsheet could be used to determine the aggregate product performance from the components the product was broken into for design and analysis. This is indeed a mathematical model, as it requires the relationship between product submodules be expressed in order to express estimated aggregate product performance. Typically however, even in the moderately complex simulation systems used to discretely model computer systems, all the math that is required is a working knowledge of queueing theory and statistics, as opposed to the underlying mathematics necessary to prove correctness of theorems.

Now, back to the subject of modeling the product's performance characteristics. How much farther a development team decides to go with a modeling exercise is mainly a function of product complexity versus accuracy of predicted results. Typically, we find that in order to achieve a consistently high degree

of accuracy in a model, the model must be more representative of the details of the actual system, and therefore may be inherently more complex. The more complex the model, the longer it takes to implement, and the higher the skill level required to implement, validate and maintain the model.

The time invested in creating the model must be offset by the benefits it will provide to the development effort. The strengths of models lie in the fact they are usually more easily implemented than the actual system under development, and can be used to answer questions key to design issues that affect product performance. In very complex products, a model is almost necessary to facilitate the understanding of module interaction and effect on overall system performance. In such a case, it is easy to justify the staffing and resources necessary to design, create, and support the product model. In simpler cases however, the decision to implement a product model is not so clear cut, and assigning important project resources to the effort may not be justified.

In all cases, however, modeling must be considered as part of the development effort which will have an effect on the outcome of how the product may ultimately perform. At a minimum, the simple "paper model" or spreadsheet must be used to sum component performance into overall product performance.

As the product becomes more complex, making design decisions which affect performance become more difficult without data to validate the decision. Models allow for experimenting with design alternatives before they are actually implemented, giving a fairly accurate idea of how the actual system will perform under similar circumstances. When given a choice of implementing actual portions of a product with the potential for redesign and recode due to performance problems, versus modeling the same circumstance ahead of the actual implementation, the choice becomes easier to make. A checkpoint should be established as part of the design effort which answers the model/no model question in all cases prior to actual product implementation.

TRACKING PRODUCT PERFORMANCE

As previously discussed, the steps of establishing global performance goals, decomposing the product into more manageable components and establishing component goals, and developing a product model are all measures intended to aid in the architecting of performance into the product, rather than measuring the product after implementation to see how well it performs. In order to allow managerial control over the development of the project from a performance standpoint, a mechanism needs to be put in place to allow for the tracking (monitoring) of progress towards meeting the established performance goals as the product is built.

A formal document is typically produced and maintained to monitor the progress being made towards meeting the formally established performance goals. This document is referred to as the Performance Tracking Document (PTD). The format of the PTD can vary from product to product, but it typically contains the following minimum information:

- A statement of the global performance goals established for the product. The goals are stated in terms of quantifiable, measurable metrics such as response time and throughput. These are the goals which are established at product specification time with interaction from the user/customer of the product.

- Definition of the environment under which the performance tests will be performed. This includes specific hardware/operating system configurations (and variations, if applicable), as well as the types of user/transaction mixes that will define how the product is exercised.

- A description of the components into which the product has been decomposed. Typically, a product pictorial model is included which shows the interrelationships and data/control flow among the various components. Additionally, a description of the functionality and performance expectations of each component is included.

- A detailed description of the test program/benchmark which will be used to drive the product during performance testing, along with any hardware/software configuration data for specific instances of the test (varying memory sizes, number of terminals, number of discs, etc.).

- A description of the measurement tools and component instrumentation used to determine how the product is behaving, along with methods for enabling measurements if they are not enabled at all times.

- A section whose primary purpose is to display projected performance versus actual performance over time. This is the true tracking mechanism, which at a glance should show progress on the overall product goals as well as the individual components. An area for remarks and comments should accompany the display of each component's performance history to explain why sudden shifts in performance (plus or minus) may have taken place.

- Usually an appendix is included to the PTD which describes the overall purpose of the product, the environment in which it will be used, and the importance of meeting certain performance goals in specific circumstances. This appendix continues to remind project management and performance tracking personnel of the "big picture" so the trees still stand out from the background of the forest.

The PTD is usually published at regular intervals from 2 weeks to a month, depending upon the frequency of updates required by management. Overall, the PTD provides a history of how the performance effort progresses (or in some cases, regresses) over the life of the product development cycle. It becomes quite obvious, for instance, when a major design change is implemented which affects performance either positively or negatively, as the change in component and product performance will be reflected in a time frame (via the PTD) which coincides with the implementation of the change. The PTD is also a forum where issues which will have an effect on product performance can be aired for

management perusal and can stimulate action to solve problems before they occur.

OTHER TOPICS

There are several other components which make up the SPC in addition to those discussed, some of more consequence than others. Three topics not covered in this paper which are part of the SPC and to which significant work has been devoted at HP are Performance Measurement Tools, Benchmarking Technology, and Workload Extrapolation and Characterization. Separate papers have been submitted which cover our efforts in the Tools and Workload areas and work is progressing on exposing our Benchmarking work in future efforts.

Figure 1 is a synopsis of the SPC showing the major points to which individuals or groups have been assigned to carry out the indicated tasks and the overall flow of the SPC as implemented at HP.

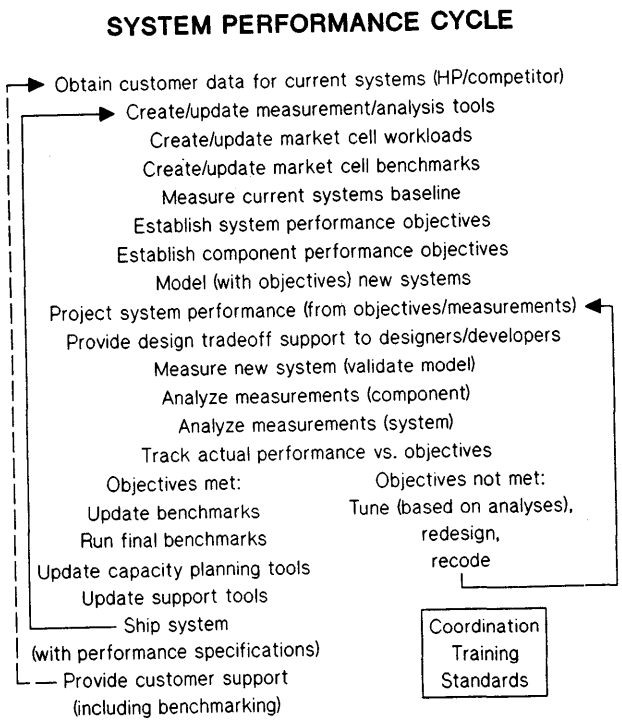


Figure 1.

FINDING PERFORMANCE PROBLEMS IN EXISTING PRODUCTS

Until all new products are engineered with performance in mind, we will likely continue to find areas within these products where performance problems are occurring. Besides, it may very well be that when the product was designed and implemented, performance was not an issue and the product performed in a satisfactory manner as far as the end user was concerned.

Well, times change, don't they? Additional terminals have been added to the system, the data base has grown and additional data sets have been added. The MIS department has decided to run background batch jobs at a low priority during the day because they feel it won't impact system response "that much", and a new set of applications have been added for the finance department. The performance of your product which at one time was considered adequate, is now driving the users crazy pressure is increasing to do something about it. What now?

Many of the principles applied to a new product can be applied to products which already exist. Global performance goals need to be established which the product must meet to be again acceptable to the users. Product resource consumption should be determined (an easier chore now...it exists to be measured!) and the resource demands of this product must be compared to the typical system aggregate resource demand to determine what percentage of the various system resources the product requires.

One of two possible paths can be selected at this point:

- Resource demand of the product appears to be in line with the work that is being done. This would imply that no significant gains in performance would be seen in relation to the effort expended to "tune" the product. Additionally, this usually implies the hardware/software system is "tapped out" in the current environment and additional analysis should be performed to alter the usage characteristics of the machine, or consider upgrading to a system with more resources.

- Resource demand of the product appears to be out of line with the work being done. Again, analysis can be performed regarding the usage patterns of the system, or a decision can be made to tune the product for better performance.

If the decision is made to attempt to tune the product, it should be analyzed and determinations made as to how to decompose it into smaller, more manageable components, just as the "new" product would be decomposed in order to aid in performance monitoring and design tradeoff analysis. The components should be measured, instrumented if necessary, and analyzed as to what particular part(s) of the product seem(s) to be contributing to the performance bottleneck and appropriate action taken to correct the problem.

Depending upon the level of undertaking, simple models can be developed to aid in major design change decisions to weigh the effect of the change on product performance, and to estimate the amount of system resources that may be required of released, depending on what is changed. Finally, if the tuning effort is major enough, a tracking document can be set up to allow the detailed monitoring of the changes made versus requirements to be met as the effort proceeds.

IN CONCLUSION

The thesis presented in this paper is a simple one; that a product can be developed from scratch with performance criteria specified beforehand, with a high probability that the performance goals established in the beginning will be met or the product should not be built.

From a practical standpoint, this concept makes a lot of sense. There just aren't too many products, no matter how great the functionality, whose "poor" performance can be tolerated over an extended period of time. It just costs too much money and has a tendency to develop emotional overtones after a while.

Therefore, why expend scores of man months pursuing the design and implementation of a product that will perform poorly and probably consume excessive system resources, if there is a good chance of the product being a failure? The effort is usually expended at some point to interject a certain level of performance into a product, although it is much more effective to do it at the beginning and carry it on through to completion, rather than to have the remark made during the preliminary acceptance test that "The product does everything I want it to, but I haven't got the time to wait for it to get done. Show it to me again when it's faster...".

"EXPERT SYSTEMS: LET'S BUILD ONE TOGETHER"

Frank J. Ingrassia
Innovative Management Solutions, Inc.

ABSTRACT

Talk is cheap, and there has been plenty of talk in the past few years about Expert Systems and their applicability to the Computer Performance Evaluation (CPE) area. I'll include myself among the great procrastinators, preaching AI, but doing much too little about it. The problem with Expert Systems can be stated in one sentence: they are very hard to build. Period. Knowledge Engineering is an art form in itself, and the languages of AI are difficult, if not bizarre, in which to write programs, especially for those used to Fortran, SAS, Assembler, et al. So, this paper is for everyone who wants to build an Expert System, but can't get past the first stumbling blocks. We will talk about organizing the knowledge, and the logic of the program, as we attempt to construct an Expert System for a CPE application. We will also use and discuss one of the AI languages, Prolog, and hopefully make some sense of it. It is my goal to unravel and simplify the construction of Expert Systems to the point where everyone will feel comfortable in building one. To accomplish this goal, I shall have to overcome the same obstacles we all stumble over. So join me now, as we tackle Expert Systems: let's build one together ...

INTRODUCTION: SIGNS OF LIFE NOTED

For more than two decades, academic and research institutions have explored the topical area of Artificial Intelligence (AI), from rudimentary (but not elementary) efforts to teach a computer to play a better game of chess, to more complex applications like medical diagnosis [1], geological analysis [2], self-psycho-analysis [9], and other "Expert" Systems. The author has previously explored the question of what constitutes an expert system, and the philosophical question of computer intelligence, in a prior paper [3]. Rather than continue to ponder what is ultimately in the eye of the subjective beholder, we will focus our attention on the construction of a real, live (?) Expert System.

The field of Computer Performance Evaluation (CPE) would seem to be a suitable domain in which to establish an expert system. Much is known about the cause and effect of tuning parameters, and there exist a plethora of rules of thumb (ROTs) and practical experiences from which to establish an impressive knowledge base for an "expert" on MVS, for example. Unfortunately, the data required to process even a subset of the MVS universe is quite substantial, as IBM researchers discovered. It turned out that more effort was required to develop, code, and maintain data reduction tools than was necessary to implement the inference mechanism and knowledge base in a recent IBM effort concerning the DASD I/O portion of MVS [4].

Since we wish to concentrate our efforts on building an expert system, rather than a data collection / reduction tool, we will choose an area of CPE that does not have data to input in machine-readable form. There are many fine data collection, reduction and analysis tools already established by prominent vendors in the CPE community. We shall leave the task of extending their work into the Expert Systems arena to these vendors, and take our departure into a more pristine environment: software engineering. The author has accumulated much experience in new application design and performance engineering concepts for large online systems, working with several modelling tools in a concerted effort to predict the performance and capacity of applications under development [5], as well as to illustrate the positive and negative impacts of engineering certain design changes [6]. For this study, we will select the universe of software engineering for applications under development, and concentrate on one domain within that universe, namely IMS DB/DC [7]. As an implementation vehicle, we have chosen the PROLOG language, an acronym for Programming in Logic. This choice was made predominately on usability and the widespread acceptance of this AI language in general. PROLOG is implemented for the mainframe as part of IBM's Expert System Development tools [8] under VM. Several versions of microcomputer compatible PROLOG are also available. The particular version we will be working with is TURBO PROLOG [10], a program product of Borland International. This version seems to be a very productive implementation, and comes with a variety of support tools called the TURBO PROLOG TOOLBOX [11]. Portability to the mainframe should hopefully be a minor task, especially in anticipation of IBM's obligatory announcement of PROLOG availability under MVS. Meanwhile, we can devote hours of R&D to our standalone IBM PC/AT, COMPAQ, or Compatible, rather than require extensive mainframe time, or the use of a special purpose LISP machine, to pursue our goal of building an Expert System. The ubiquitous presence of Personal Computers in all segments of our industry also helps to make this implementation strategy a practical choice. Besides, we are trying to unravel the mysteries of constructing expert systems: what better device than the common, harmless, garden variety PC ?

To begin with, we must approach this expert system construction with some specific goals in mind. We are concerned about the design of IMS online systems, but we haven't specifically said what we want to accomplish in that domain. Our goals are these:

1) to construct an expert system knowledgeable in IMS internals and current hardware;
2) build a user-friendly interface to solicit IMS transaction design information;
3) calculate the expected response times, throughputs and utilizations;
4) evaluate the results vs. user-defined performance objectives, offering recommendations and trade-offs on design issues, to achieve those objectives.

An ambitious project, to say the least ! Let's also say what we are NOT trying to do: we are not trying to develop another modelling tool. Rudimentary (read "simple") performance calculations are all that are planned. We are much more concerned with making intelligent design choices, not by trial and error, not user-driven, but DATA DRIVEN. If all works according to plan, the results of design input will dictate what recommendations and design alternatives are presented. Realistically, we do not expect to complete all the work in 1987. However, enough has or will be achieved to demonstrate the viability of expert systems technology in solving real problems in Software Engineering and CPE. Let's now begin: we'll learn together.

PROLOG, THE LANGUAGE: PROGRAMMING IN PURGATORY

Forget what you know about conventional programming: none of that will help you master the PROLOG language. In fact, the author is convinced that those fresh out of

college, or non-DP altogether, have a distinct advantage in learning to code in PROLOG! The language itself is devoid of the things we take for granted in COBOL, Fortran or PL/1. Simple things, like GOTO statements, or DO loops, for instance: you will not find them in PROLOG. There is likewise no assignment statement! The simple counter X=X+1 is not available. PROLOG is different: it is not a procedural language at all. We don't give PROLOG instructions: "do this, do that, then do this". Rather, we give the program "facts", and operational "rules" concerning those facts, and it figures out how to solve the problem.

The TURBO PROLOG compiler is a "backward chaining" implementation. In this methodology, IF-THEN rules start out with a goal and proceed backwards until all the premises satisfying the goal have been proven. This is sometimes referred to as "goal driven reasoning", because the process is driven by the goal it attempts to prove. Other AI systems use "forward chaining", where the IF-THEN rules are applied to facts in forward motion, until the facts culminate in a recommendation. That method is also referred to as "data driven reasoning", because the solution is achieved by the existence of an initial set of data. There are a few other concepts to master as well. As stated, there is no formal assignment statement in PROLOG. Instead, a pattern matching process called "unification" gives values to its variables. The variables can be considered either "free" (having no value) or "bound" (bound to a particular value), and often oscillate between these two states as PROLOG moves from clause to clause. The "clause" is PROLOG's equivalent of a statement. It is written in sentence form, usually presenting an IF-THEN case, only backwards. The conclusion comes first, followed by the conditions. For example,

```
domore if write ("Another?") and readln (Ans)
          and Ans=y.
```

This says that "domore" will be true (succeed) IF the message "Another?" is written on the screen, AND a response is read (Ans), AND that response was a "y" for Yes. Isn't this fun? Obviously, "domore" is a condition in some other clause which will only succeed if all these conditions are met. This is what PROLOG is all about: truth (or falsehoods) and succeeding in your clauses, leading ultimately to your goal. The language has a few other idiosyncrasies worth mentioning. Symbols have no meaning. All PROLOG symbols and clauses and "predicates" (action verbs) are written in lower case. Only Variables are written in upper case. The language uses "recursion" to allow clauses to be both input and output driven. Remember our mention of "free" and "bound" variables. A PROLOG clause can be used to test if a condition exists (or is true) or to prove a goal because the relationship (or clause) exists. For example,

```
calc(x,y,z) if X=4 and Y=Z/X.
```

If this clause is referenced with Y free and Z bound to some value, then X will be 4 and it will succeed. However, if called with X bound to 3, it will surely fail because X must =4 as one of the conditions for truth. Thus, the clause above could perform the calculation OR test whether X has the value 4. Admittedly, a crude example, but it will make more sense, in light of the discovery that PROLOG allows multiple clauses of the same name and executes them, in sequence, trying successive clauses as the prior ones fail. Thus, we could have 5 successive "calc" clauses, with X having values of 1 through 5, if that was our intention.

When searching for clauses that meet the goal of the program, PROLOG will use a technique called "backtracking". This occurs when subgoals (conditions which are part of the goal) succeed, but others fail. PROLOG will backtrack to the last successful subgoal (or condition) and try another set of clauses. You can control backtracking via the cut symbol ("!"), telling PROLOG that you are satisified with 2 out of 3 conditions, for example. You can also force PROLOG to keep repeating a clause, using recursion, until it fails, by using the special predicate "fail". This might be helpful to print a list until there is nothing left to print, for example. The language composition includes five main sections:

1) DOMAIN — where descriptions of PROLOG objects occur, including their type (character, integer, real, string, etc.). This is equivalent to DECLARE in PL/1 or INTEGER * 4 in Fortran.

2) DATABASE — where those variables/predicates which will make up the knowledge base are stored. This is equivalent to COMMON in Fortran, an incore dynamic data storage area.

3) PREDICATES — the "form" of subsequent clauses must be declared, so that PROLOG can know the relationship of the data used in the clause. This is akin to declaring a FUNCTION in Fortran.

4) GOAL — this is the ultimate objective the program is trying accomplish, or prove. The goal may be complex, and include many subgoals which must also be satisfied.

5) CLAUSES — are sentence oriented statements of the language. Here, "Rules" and "Facts" are described, which are then used by the program to solve its goal.

The TURBO PROLOG implementation used also contains many standard "predicates", which perform useful functions. The "fail" predicate has already been noted. The following are some predicates that perform and control I/O:

```
makewindow    - draws a window on screen
clearwindow   - erases contents of window
removewindow  - removes a window from screen
cursor        - positions the cursor at x,y coordinates
window_attr   - changes color attributes for window
shiftwindow   - moves to another window
scr_attr      - sets a character position's attributes
scr_char      - reads/writes a character at position
field_str     - read/writes a string of characters
field_attr    - sets a string's attributes on screen
write         - displays data on screen or other device
writef        - formatted output writer
readln        - reads a line of data (string or symbol)
readint       - reads integers
readreal      - reads real numbers
readchar      - reads a single character
file_str      - reads the contents of an entire file
nl            - skip to a new line
```

TURBO PROLOG has a full complement of arithmetic operators, and several useful Built-in functions, including:

ARITHMETIC OPERATORS: +, -, *, /, (,), <>, ><, $hex

RELATIONAL OPERATORS: >, <, >=, <=, =, <>, ><

PREDICATES: bitand, bitor, bitnot, bitxor, bitleft, bitright

BUILT-IN FUNCTIONS: mod, div, abs, cos, sin, tan, round arctan, ln, log, sqrt, random, exp.

TURBO PROLOG has a fair complement of graphics capability, including:

```
graphics      - set mode CGA/EGA
dot           - draw points
line          - draw lines
```

```
penup          - lift the pen (turtle graphics) *
pendown        - place the pen
pencolor       - color the pen
forward        - move it forward
back           - move it backward
right          - move it to right
left           - move it to left
```

* NOTE: turtle graphics simulate "joystick" control of an imaginary pen on the screen.

TURBO PROLOG has file I/O capability as well, in the following predicates, which also operate on any other device (PRN,COM,etc):

```
openread       - open a file, for Read only
openwrite      - open a file, for Write only
openappend     - open a file and append to the end of it
openmodify     - open a file for read/write
closefile      - close a file
readdevice     - read from file
writedevice    - write to file
filepos        - position pointer in file at record,byte
existfile      - test for file's existence
deletefile     - erase a file
renamefile     - change file name
eof            - test for end of file condition
flush          - flush the file Buffers
```

TURBO PROLOG offers many ways to manipulate strings and lists; some of these predicates are:

```
frontstr       - split a string, peel off front "n" chars
str_len        - finds length of string
isname         - tests if string is a valid PROLOG name
frontchar      - pick off front character of string
fronttoken     - split string into a list of tokens
char_int       - convert character to integer
str_char       - convert string to a single character
str_int        - convert string to an integer
str_real       - convert string to a real number
upper_lower    - convert upper to lower case letters
```

There are several miscellaneous predicates available, which do some useful things for the programmer:

```
findall  - find all occurrences of a variable in a List
free     - frees a variable, or tests if free
bound    - tests if a variable is bound
inkey    - reads a single char from any input device
beep     - produces the TTY "Bell" equivalent
sound    - produces a range of sounds
dir      - will produce a DOS file directory
concat   - concatenates strings
time     - returns current time of day
date     - returns current date
```

Finally, there are the database (knowledge base) controlling predicates, of the utmost importance in manipulating goals, clauses and searching for solutions:

```
asserta  - inserts a fact before all others in dynamic
           database
assertz  - inserts a fact after  all others in dynamic
           database
retract  - removes a fact from the database
save     - saves  the  dynamic database into a file
consult  - reads a file and restores the dynamic data-
           base
readterm - reads facts from a file
```

There are several syntactical things to know. TURBO PROLOG uses some special characters:

```
:-   if
,    and
;    or
!    cut
|    splits head/tail of a list
[]   a list
*    list follows
_    anonymous variable
```

and the word not, implying negation. A full explanation of the syntax and uses of TURBO PROLOG language may be found in the user's guide [10]. Noteworthy is the entire framework around Borland's TURBO PROLOG facility. It contains its own EDITOR, and TRACE facility, essential for following the logical path of your programs. The compiler also generates standalone, EXECUTABLE object code, in contrast to most interpretive versions of the language. A highly recommended companion product is the TURBO PROLOG TOOLBOX [11], which contains a number of canned PROLOG programs which may be "included" into your own program to process windows, menus, status lines, context sensitive help screens, DOS and directory operations, BIOS calls, and other useful functions. A veritable cavalcade of sample programs and usable source code come with each of the products, which will get users on their way in no time. Before closing this section on Prolog, The Language, let me point out that Borland's TURBO PROLOG is but one of several microcomputer versions of the language available. As a starting point for those interested in acquiring a PROLOG compiler, there exists a fairly recent comparison of 14 different PROLOG compilers conducted by AI Expert [15], which is worth reviewing. As for TURBO PROLOG specifically, there are some pitfalls and limitations that you should be aware of:

1) Don't use too many variables in a single clause: 100 is the maximum. You can get around this by calling another clause from the primary clause.

2) Close windows when they are not in use, especially Toolbox #80-85, which can be created multiple times: about 22 open windows is the maximum. A simple set of clauses like the ones below may be helpful, which close all windows except window #1, the primary screen:

```
closeall:- shiftwindow(X), X<>1, removewindow, closeall.
closeall:- shiftwindow(X), X=1.
```

3) The Trace compiler directive adds about 200 16-byte paragraphs to memory requirements, which may need adjustment via the CODE=nnnn compiler directive.

4) Use the Dynamic Database incore to pass data around, rather than having clauses with many parameters. This works like a COMMON area in Fortran.

5) Data may be passed to clauses called by other clauses. This is like Subroutine calling in other languages, as data values may be passed to and returned from the clauses invoked.

6) Use Menu processing to provide external control of the program's execution flow. Menu selections may be hard-wired to a trigger clause, which in turn invokes a series of clauses: the menu is the goal, and can always be satisfied; the menu options are the sub-goals, which you may choose to solve.

7) Use CUT (!) and FAIL judiciously, to prevent memory or stack overflow conditions. CUT will stop processing as soon as enough of the clause's conditions succeed. FAIL will invoke recursion until the clause fails, then move on.

8) Break up large programs into smaller, more manageable ones. PROLOG has memory limits equivalent to RAM size. Use the dynamic database to pass data & facts completed so far to the next program in a chain, via save

and consult.

9) Use TRACE to follow your logic; use the DIAGNOSTICS compiler directive to see how much memory you are using, as well as which variables / predicates are not being actively used in the code. Use the "storage" predicate to dump the current Stack, Heap and Trail sizes: manage memory efficiently.

10) Play and learn with one program at a time. There are literally hundreds of sample programs provided, and each demonstrates a particular feature or routine. For example, how to write lists of "n" variables, how to build a database manager, how to append things to a list and find them later, how to build accumulators, screen generators and controllers, how to do file I/O, etc. Master one at a time and don't write numerous of lines of code before you start testing: keep it simple and you will be most productive, and test each new clause of the program as it is added, using TRACE facilities to ensure that it does what you require. See examples of source code provided in the next section for further illustrations of these techniques.

KNOWLEDGE ENGINEERING: KNOWLEDGE IS POWER

Having completed our excursion into the semantics and facilities of PROLOG, we now turn our attention to the task at hand. Our first major task is at the data level: we must design our Knowledge Base for IMS DB/DC. In all seriousness, this is a trial and error task requiring considerable time and effort. We must go through successive iterations of the database design as we begin writing and testing the code. The format of the data and data types have significance. Shall we use numbers indicating different scenarios, i.e. 1=MPR, 2=BMP, 3=WFI, 4=EMH, or shall we use symbols (or character strings) to represent the data? The final choice, it turns out, is largely a matter of programming style. If you employ menu selection, for example, PROLOG returns the choice number you selected on input. Now, you can convert this number into its equivalent symbolic representation, or just look up the number! Designing an efficient knowledge Base is very similar to the task a Database Administrator (DBA) might perform for IMS. Questions like "Is this data element absolutely necessary?", or "Can this element be calculated from other elements?", and similar situations need to be addressed. Considering that all of the knowledge base may need to be memory resident at some point in time, or stored in files, we should be conscious of the same storage efficiencies as with MVS. Data is also grouped into fact clauses by combining similar and related elements, just like in other databases. Another decision must be made regarding the data location itself: should it be hard-coded into the program, as clauses, or stored in a file for consultation later? Similarly, knowledge acquired by executing the program (read "created at runtime") also needs to be thought out, and designed, just as the permanent knowledge base. There is no magic secret to designing an efficient knowledge base, but it is best accomplished by observing three rules:

1) keep related data in the same clause;
2) eliminate redundancy and calculatable elements;
3) shorten data formats wherever possible, using symbols.

Our IMS expert system employs several databases, and three main program components. The first program, CMGDESC, is used to solicit the design of transactions from the user, who describes what the transactions will do. These descriptions of the transaction profile are created and stored in an internal database, which is saved into a file at the conclusion of the program. This file, a Knowledge Base describing the user's transactions, becomes the input Knowledge Base for the second program, CMGCALC, which calculates the path lengths and expected performance of the transactions. These are then added to the Knowledge Base, and passed (via file) to the third and final program, CMGANAL, which analyzes the calculated performance vs. the user's performance objectives, and makes decisions and recommendations for improving the design. These three programs are used in concert to satisfy our overall goal of designing efficient IMS transactions. See Figure 1 for the logical flow of the data and the Knowledge Databases employed. They are three (3) separate programs to economize memory.

Now that the data flow has been ascertained, and the various internal and external databases identified, let us look at some sample "knowledge" contained in each database. Examining Database 1 (from Figure 1), the Internal Hardware characteristics database, we find knowledge of the form:

```
                cpu_char (cpuname, #engines, miprate)
      e.g.,     cpu_char (3090-400E, 4, 61.50)
```

to describe various CPU characteristics, needed for our response time and capacity calculations. Also in this database are device characteristics, of the form:

```
                dev_char (devname, seek, transfer, revtime)
      e.g.,     dev_char (3380, 16, 3.0, 16.7)
```

Additionally, certain default numbers for IMS datasets and system libraries, like Buffer Hit Ratios, Syslib Blocking Factors and other similar information are contained herein, to form a default pool of IMS options in a well-tuned environment.

Database #2 is the PROJECT database created by CMGDESC which describes, in PROLOG terms, the Transaction Life Cycle. Many projects may be examined in our conceptual system design, so we'll give each a project name, and qualify all datasets with ".PRJ". Update capabilities are an obvious future consideration, based on the results of our analysis by the "expert". Database #2 is the epitomy of PROLOG structure in its purest form:

```
                project (projectname, status)
      e.g.,     project (CMGDEMO, 0)

                lso (type)
      e.g.,     lso (S)

                logging (option)
      e.g.,     logging (dual)

                thecpu (cpuname, #engines, miprate)
      e.g.,     thecpu (3090-400E, 4, 61.50)

                adevice (devname,seek,transfer,revtime)
      e.g.,     adevice (IMS001, 16, 3.0, 16.7)

                afile (dbdname, accmeth, blksize)
      e.g.,     afile (Myfile01, HIDAM, 4096)

                indexfor (ixname, dbdname)
      e.g.,     indexfor (Myindex1, Myfile01)

                liveson (dbdname, devname)
      e.g.,     liveson (Myfile01, IMS001)

                afpdb (dbdname, option)
      e.g.,     afpdb (MyMSDB01, Pagefix)

                runsin (txclass, region)
      e.g.,     runsin (4, Region01)

                runsat (region, priority)
      e.g.,     runsat (Region01, 16)

                argn (region, txclass 1/2/3/4)
      e.g.,     argn (Region01, 12, 10, 2, 1)
```

```
          atlc (tlcname, tps, pgmsize,  region,
                acbopt, lang, preload, inquiry,
                mode, imstype, txclass, PLtype,
                pathlen, insegm, insize, inflds,
                outsegm, outsize, outflds, spaloc,
                spagu, spais, tpaccess)
e.g.,     atlc (Tran001, 100, 512, MPR, DOPT,
                COBOL, YES, NO, SNGL, FF, 12,
                LOC, 12000, 2, 1024, 50, 4,
                2048, 100, CORE, 2, 2, VTAM)

          adbd (tlcname, dbdname, usesix, gu, gn, is,
                ir, ds, dr, de, re, op, pos, fld)
e.g.,     adbd (Tran001, Myfile01, YES, 2, 4, 2,
                 0, 0, 0, 1, 1, 0, 0, 0)
```

As you can see from the preceding examples, we have stated the description of our various transactions in sentence - like form. Most important to our work is the definition of "atlc" and "adbd", which define the transaction life cycle (tlc) and database descriptions (dbd) respectively. Those familiar with IMS will notice many familiar acroynms and options above: we will not explain them further here. Suffice to say that they are IMS-specific, and carefully selected.

Database #3 is an internal database representing the actual pathlengths for various IMS system activities, as one might find in CRYSTAL [12], SNAP/SHOT [13] or other [14] modelling tools. As this data is largely proprietary in nature, actual values cannot be included herein. However, the form of our third database is representable, as follows:

```
ims_msgin (tpaccess, inquiry, P/L)
ims_msgout (tpaccess, inquiry, P/L)
ims_sched (regiontype, P/L)
ims_acbload (regiontype, acbopt, P/L)
ims_pgmload (preload, language, P/L)
ims_appl (P/L Type, Language, P/L)
ims_mfs (in/out, P/L Flds, P/L Segm)
ims_spa (spaloc, function, P/L)
ims_iopcb (mode, function, P/L)
ims_dli (accmeth,function,six, SP/L, XP/L, YP/L, NP/L)
refindex (usesix, factor)
ims_fastpath (accmeth, function, P/L)
ims_log_phy (accmeth, function, ratio)
ims_buffpool (area, fix P/L, nofix P/L)
ims_fixbuff (area, ratio)
ims_pio (accmeth, fix P/L, nofix P/L)
ims_log (P/L)
ims_iofactor (area, ratio)
```

The above list is a nearly complete summary of the types and formats of the IMS path length internal database, also illustrating the relationships between the data elements.

Database #4 is the output of the CMGCALC performance calculation program. It contains summary level data which is the result of applying the path lengths to the transaction descriptions, and calculating simplex service times, response times and utilizations. Some of its records resemble the following:

```
          exec (tlcname, txperhr)
e.g.,     exec (Trans001, 8000)

          inclass (txclass, tlcname)
e.g.,     inclass (12, Trans001)

          uses (CPU, tlcname, svc)
e.g.,     uses (3090-400E, Trans001, .402)

          doesio (dbdname, tlcname, I/O count)
e.g.,     doesio (Myfile01, Trans001, 12.2)

          fileio (dbdname, %utilized)
e.g.,     fileio (Myfile01, .03)

          cpuse (tlcname, %utilzed)
e.g.,     cpuse (Trans001, .044)

          devuse (tlcname, devname, svc)
e.g.,     devuse (Trans001, IMS001, 10.382)

          devio (devname, %utilized)
e.g.,     devio (IMS001, .092)

          filuse (tlcname, dbdname, svc)
e.g.,     filuse (Trans001, Myfile01, .938)
```

The above are some samples from the 4th database, which summarize a transaction's impact on the system configuration proposed. CMGCALC takes in descriptions of the Transaction Life Cycles, and attendant DBD, REGION, IMS System and Configuration data, and calculates expected results in this format.

The final database, CMGANAL.DBA, will contain the IMS design analysis rules, to be applied to the summary AND detailed descriptor information collected and asserted by CMGDESC and CMGCALC. These tuning rules will analyze the design and match the calculated results against user - supplied PERFORMANCE OBJECTIVES. As of this writing, formulation of the 5th and final database is incomplete.

Anticipated rules will operate on several levels:

1) General Configuration Efficiency
   - CPU utilization
   - device utilizations & data rates
   - file utilizations

2) IMS System Efficiency
   - region/transaction distribution
   - region occupancy time
   - IMS Syslib utilizations
   - Concurrency and overheads

3) Application Program Efficiency
   - overhead functions for system services
   - detailed I/O analysis
   - file and access method effectiveness
   - transaction profiling and characterization

4) User Objectives & Expectations
   - throughput analysis
   - response time analysis
   - workload decomposition

By applying facts and rules in the above categories, it is anticipated that we should be able to conduct a relatively complete analysis of the proposed TLC design, and recommend some appropriate modifications in areas deemed to produce the greatest benefits in performance efficiency.

DEVELOPING THE EXPERT SYSTEM: ROME WASN'T BUILT IN A DAY

As previously stated, the purpose of our Expert System is to evaluate proposed designs of IMS transactions and to recommend improvements and enhancements based on user - defined objectives. This is our target system, still under construction. However, the purpose of this paper is to illustrate how such expert systems might be constructed. We have spent considerable time explaining the facilities available in TURBO PROLOG, as well as the design and content of our Knowledge Base. This section deals with program construction, and contains samples of working code which illustrate the implementation strategy of our proposed system.

We have made mention of using menus, both to gather data in a user friendly fashion, as well as to direct PROLOG to address major subgoals, or program sections, in our system. Figure 2 shows the entry menu, the primary goal (run) and how the various choices in the menu invoke

subgoal processing. Menu choices can be executed at multiple levels. Selecting option 1, "Create a Project", invokes the build predicate, which in turn offers a second menu as defined in Figure 3. This menu presents the user with a choice of various things to describe for the Project, including:

- Setup IMS Sys Gen
- Set Configuration
- Database DBD Gens
- Define Transaction
- Define Regions/Mix
- Save Project & Exit

Construction in this form allows the user to enter any number and any order of descriptions. He or she may skip the IMS gen, enter a few transactions, define a region, go back to transactions, etc., and save the project database whenever suitable. Other primary menu options will allow the updating of partially completed projects later. Users may even redefine certain values which have only one definition, and the latest definition will always take precedence by utilizing PROLOG's asserta database insertion device, at the front of the dynamic database.

The simple task of gathering user data about the design, and the inference of that data, is illustrated in Figure 4, the defrgn (define region) predicate. Notice the use of TURBO TOOLBOX tools (changestatus, lineinput_leave), as well as standard PROLOG data drivers (makewindow, write, readint). Most important is the asserta section, which stores the knowledge acquired into the incore database. Finally, observe the looping construction of morergn: it returns to defrgn execution if the answer to "Another RGN?" was yes; else, it fails and drops to the second morergn clause, which invokes the closeall windows routine.

In Figure 5, the parameter data, in the form of variables, is passed to the chkindex clauses. If USIX="y", meaning that secondary indexing is requested, then the routine proceeds to gather additional data about the index, and makes the appropriate assertions to the database. However, if this clause fails, the next chkindex clause is tried, and succeeds with USIX="n", or no secondary index. It then becomes basically a NOP instruction, taking no further action because none is necessary. Another useful feature of PROLOG is it's ability to work with "lists". Consider the use of findall in the setdevice clauses in Figure 6.
It searches the internal knowledge base for "dev_char" clauses, and compiles a list of their device names. The list is written by the wrlist predicate, also in Figure 6. It's purpose is write 7 devices at a time, skip to a new line, and write 7 more, until the list is empty. Notice we also provided the user with a capability to define new devices using the DEF command. In getdev clauses, if Adev = "DEF", a new device, and it's characteristics, are solicited from the user. Otherwise, the dev_char clauses are searched for a match against the device type, and asserted if found. Lastly, we fall through to a third getdev, with an "anonymous" variable (_, meaning any value) for Adev: if you come this far, you probably spelled something wrong, so back-track to disks and start over.

PROLOG also has arithmetic ability, as displayed in Figure 7. Here, code taken from CMGCALC shows a portion of the pathlength calculations for a transaction life cycle. It consults the "ims_log" portion of the knowledge base, asking PROLOG to reference the knowledge base and return the value of LREC, a path length for physical logging. It then performs some calculations on other variables, using LREC in the process, and completes with a call to append, a routine which adds things to a list (in this case, a calculated value LOGREC, appended to the back of LIST8, to form LIST9). Note that these are just some of the clauses in the dotlc predicate, which calculates the entire pathlength of a transaction, using the sumlist clauses.

These excerpts from working code written in PROLOG are included to illustrate the relationships of data and predicates, and the power of the language itself to express complex manuvers in simplistic terms. In all fairness, PROLOG is not an easy language to understand. However, with practice, a great deal can be accomplished in a few lines of code. The author estimates that 5 to 10 times fewer instructions are required by PROLOG than by other procedural languages to perform the same task. As part of our investigation into PROLOG's capabilities, a complete database management system, with full screen input, update search by key and report generation was built, tested and operational in less than 3 days: that's productivity! However ...

As hinted in the section heading, the thorough development and testing of an expert system is not an overnight project, regardless of the power and flexibility of the language. At this stage, CMGDESC, the IMS Transaction descriptor program, is complete, tested and operational. It can be used to describe any IMS transaction, including Fast Path, and constructs the proper data driven knowledge base. The second program, CMGCALC, is also working, and in the final stages of testing and verification. The final component, CMGANAL, is still in design mode, as is the database of tuning rules it shall employ. In retrospect, the hardest part of building expert systems can be summed up in one statement: Knowledge Engineering. Still, we have come a long way toward demonstrating the viability of expert systems in solving today's problems, and we are quite satisfied with our results to date. Given more time and effort, we intend to learn even more in the future, and look forward to the eminent transition of AI from research to practicality. As the saying goes: "Two out of three ain't bad !"

ESOTERIC ISSUES: I THINK, THEREFORE I AM ?!?

The author would be reticent not to express a few comments on the potential and future uses of expert systems technology. It is obvious at this point that existing systems can be rewritten and duplicated using AI, with minimal effort. However, that is not much of an accomplishment. We need to push the limits of imagination further, and contemplate new uses for this emerging opportunity. We know that the knowledge of several experts can be pooled, making the resultant AI system smarter than any one of it's human contributors. More work needs to be done on the pure heuristics of self-learning and adaptation. Self-learning methods to date have been in the form of historical success/failure tracking, teaching systems to learn from their mistakes or triumphs. Further techniques are required that can emulate the ability to be inquisitive perhaps, or evolve in understanding. At some point, expert systems must have the ability to request more data, leading the conversation, rather than being driven by our limited goals. Perhaps a freestanding, freethinking expert system, concentrating on a suitable knowledge domain, might someday reconstruct the patterns of it's facts and rules to arrive at new conclusions we had not anticipated. As cycles and parallelism in CPU's become more abundant, it may be that our greatest opportunity is to program an expert system with rules about how to acquire knowledge and combine concepts, and let it crank away, searching for new ideas and formulating new data relationships that are beyond our own capability to establish. Ultimately, emotional response, personality and introspection might be envisioned, with a dash of humor and a dose of morality, which might just culminate in a complete, free thinking, Actually Intelligent system. We stand at the threshold of discovery: let's make the most of this rare opportunity to be creative.

A PROLOG-based Expert System for Tuning MVS/XA

Dr. Bernard Domanski ***

The College of Staten Island / CUNY
Bell Communications Research, Inc.

ABSTRACT

This paper will discuss some of the issues involved in building an Expert System that embodies tuning rules for IBM's MVS/XA operating system. To understand the components of an Expert System and their functions, PROLOG on an IBM PC (Turbo-PROLOG from Borland International) was chosen as the development environment. The paper will begin by defining the key concepts about Expert Systems, Knowledge Engineering, and Knowledge Acquisition. The reader will be given a brief overview of PROLOG, from which we can explain how an inference mechanism was developed. Finally, the paper will describe the Expert System that was developed, and additionally will provide a set of key issues that should be addressed in the future. It is our overall objective to provide new insight into the application of AI to CPE.

1. Introduction

In his acceptance speech for the A. A. Michelson award in 1985, Dr. K. Mani Chandy said that it takes some ten to fifteen years for research in the universities to become practical technology for industry. The field of *Artificial Intelligence* (AI) is a prime example; the last fifteen years have seen AI flourish in coming from the university sector to industry. AI languages such as LISP and PROLOG have been touted as the languages of "choice" for fifth generation computing. The Japanese have chosen PROLOG as the machine language of their logic processor for their fifth generation systems.[1] Expert System shells such as OPS5[2] and M.1[3] can help simplify and speed the development of these systems.

Considering Computer Performance Evaluation (*CPE*), some prior exploratory work has been done.[4] [5] Vendors are now emerging with *Knowledge Based* systems for CPE (ISS, Boole & Babbage).

Although AI has had a long history, the application of AI to CPE is still immature. In CPE, many performance analysts have developed a set of "rules-of-thumb" for tuning large systems. Typically, this set takes five years to develop. As there is a tendency to promote quality personnel within a corporation, it is *critical* to extract the set of rules from the performance "expert" before (s)he is promoted to a new position. In essence, a "technology transfer" must occur.

This paper will discuss some of the issues involved in building an Expert System that embodies tuning rules for IBM's MVS/XA operating system. To understand the components of an Expert System and their functions, PROLOG on an IBM PC (Turbo-PROLOG from Borland International) was chosen as the development environment. The paper will begin by defining the key concepts about Expert Systems, Knowledge Engineering, and Knowledge Acquisition. The reader will be given a brief overview of PROLOG, from which we can explain how an inference mechanism was developed. Finally, the paper will describe the Expert System that was developed, and additionally will provide a set of key issues that should be addressed in the future. It is our overall objective to provide new insight into the application of AI to CPE.

2. What is an Expert System?

An *Expert System* is a knowledge based reasoning system that captures and replicates the problem solving ability of human experts. Expertise consists of knowledge about a particular area or *domain*, understanding of domain problems, and skill at solving some of these problems.[6]

Domain knowledge, rather than the complexity of formal reasoning methods, is the key to solving difficult problems. Knowledge can take many forms:

- Specific inferences that follow from specific observations,
- Necessary and sufficient conditions for achieving a goal,
- Probable causes of symptoms.

Knowledge can be represented in several ways, such as rules, frames, and logical predicates. In most current Expert Systems, knowledge is expressed in *rules*, and these *rule-based systems* will be discussed here. The skill of these systems increases at a rate proportional to the enlargement of their knowledge bases. They usually explain their conclusion by retracing their lines of reasoning and translating the logic of each rule used into natural language.

There are a variety of reasons for building systems that capture human expertise:

- Experts retire or are promoted, taking their knowledge with them.
- An expert's time is not particularly well spent answering users' questions.
- Expertise may be scarce.
- Expertise may be expensive to deliver.
- Experts are not always consistent.

Figure 1 shows a diagram of the most basic components of an expert system. The *knowledge base* is usually a collection of rules about the problem domain, supplied by the expert. Problem solving knowledge is usually used in consultations between the Expert System and the end user or with other programs. The *working memory* keeps track of what the system knows during each consultation. The *inference engine* looks in the working memory and the knowledge base to see what is true at any given time to resolve queries.

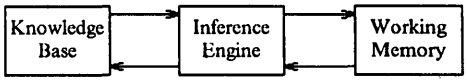

Figure 1

Consider a simple knowledge base with only 2 rules:

1. Rule 1: IF *a* THEN *b*.
2. Rule 2: IF *b* THEN *c*.

Each rule has a *premise* clause (IF), and a *conclusion* clause (THEN). If a user poses the question "IS *c* TRUE", the inference engine looks through **all** the rules

in the knowledge base and tries to find one that would conclude about *c*. It finds rule 2: IF *b* is true, THEN *c* is true. Now, if the inference engine could discover whether *b* was true, then it would know whether *c* was true. So a query is made of working memory: "Is *b* true?" Again, the inference engine examines the rules in the knowledge base, this time looking for a rule that would come to a conclusion about *b*. It finds rule 1 - this leads to asking the question "Is *a* true?" If the user responded "yes", then the inference engine would:

- erase the query about *a*,
- place the fact that *a* is true in the working memory,
- use Rule 1,
- place the fact that *b* is true in the working memory,
- use Rule 2,
- place the fact that *c* is true in the working memory,
- resolve the original query, and
- tell the user "Yes, *c* is true."

This is a simple example of a **backward chaining** system. The inference engine works backwards through the conclusions of the rules, trying to determine whether the premises are true. In a **forward chaining** system, facts would be placed in the working memory and the inference engine would report any conclusions it could to the user. For instance, if "*a* is true" were entered, the system could report that both *b* and *c* were true. Forward chaining was used in our PC/PROLOG Expert System for MVS/XA. Backward chaining systems tend to be *goal driven* - they work backward from some specific goal (*c* above). Forward chaining systems tend to be *data driven* - the system is primed with certain facts and draws any conclusions it can.

Other information must reside in the knowledge base in addition to the rules. For example, consider the user interface. How does the Expert System know what question to ask the user when that becomes necessary? This information is stored in the part of the knowledge base that describes the *a*'s and the *b*'s - the **traits** characteristic of a given problem domain. For example, the trait USERS may carry with it the prompt "On average, how many users are connected to the system?"

But when many rules are present in the knowledge base, complex consultations can occur. It can become difficult to predict what questions will be asked and in what order unless some precautions are taken. The builders of the famous MYCIN medical Expert System[7] found that doctors were somewhat bewildered when the consultation questions jumped from one topic to another: "What is the patient's age?" "What was the result of test X?" "What is the patient's name?" and so on. It becomes necessary to use more control information. For instance, the system could be instructed "Ask about traits *a*, *b*, and *c* first, then try to find the value of trait *d* by forward chaining, then ask about traits *e* and *f*, ..." This consultation and control information is also kept in the knowledge base. As will be shown later, the PC/PROLOG Expert System for MVS/XA employed this concept in its structure of its knowledge base.

It is sometimes necessary to keep even more information in the knowledge base, such as special purpose algorithms, or methods needed to retrieve information from databases that reside outside the Expert System. Thus the task of **knowledge engineering** includes more than eliciting rules from the expert; all the traits (such as *a* and *b* above), and their characteristics and accompanying control information must be identified as well.

A natural question asked about Expert Systems is "what are the advantages of using a knowledge based system?" In general, knowledge based systems extend the speed, accuracy, consistency, availability, and affordability of computation from *clerical* to *intellectual* applications. Specifically,

- *Behavior* - Users can ask "Why?" questions to show why certain decisions were made. This is in direct contrast to a traditional data processing system, where the only way to verify the system's reasoning is to simulate the system's behavior.
- *Knowledge Independence* - A piece of knowledge (a rule) can be examined and easily changed somewhat independently from other pieces of knowledge in the system.
- *Separation* - Knowledge is kept separate from the reasoning process that uses it. Building an Expert System consists of changing *knowledge* rather than program code. The expert and the knowledge engineer can examine and change this knowledge since it is ideally represented in an English-like format. Because of this separation, rule based systems can be incrementally developed with steady performance improvements.

3. Knowledge Engineering / Knowledge Acquisition

What is Knowledge Engineering? This is the term given to the extraction, description, and computerization of expert knowledge. Knowledge consists of descriptions, relationships and procedures in a domain of interest. The major task in building an Expert System is the transfer of knowledge from its source into the Expert System; this is called **knowledge acquisition.**

Potential sources of knowledge include human experts, textbooks, data bases, examples, case studies, and personal experience. Within CPE, nearly all these sources can be used to elicit performance knowledge. The prototype system developed using PROLOG used knowledge that was extracted from technical papers, IBM manuals, and personal experience.

The process of building a comprehensive Expert System can be described as an iterative, cyclic interaction between the expert, the knowledge engineer, and the system itself:

1. The expert tells the knowledge engineer what rules to add or change.
2. The knowledge engineer makes changes to the knowledge base.
3. Several tests are run for consistency checking.
4. If any problems arise, they are discussed with the expert, and we go back to step 1.
5. The expert runs the modified system on new cases until new problems are discovered.
6. If no problems are encountered in a substantial number of cases, the expert stops checking the system.

Hayes-Roth outlines stages of Expert System knowledge acquisition that roughly correspond to systems analysis and software engineering. In this acquisition model, an Expert System grows by proceeding from simple to increasingly more difficult tasks and by incrementally improving the representation and organization of the knowledge. We outline this acquisition model below.

- *Identification* - Identify the problem area and define its scope while determining the resources needed and deciding on the goals and objectives of the system. Questions that must be answered include "What class of problems will the Expert System be expected to solve?", "What data is required?" and "What are important terms and their interrelationships?"
- *Structure* - Key concepts, relations, and information-flow characteristics needed to describe the problem-solving process are defined. Related questions might include "What is given and what is inferred?", "How are objects related?", and "What is the information flow?"
- *Formalization* - Concepts and relations are mapped into a formal structure suggested by the Expert System. Related questions include "What kinds of questions should be asked to obtain data?", or "What is the cost of data acquisition?"
- *Implementation* - A knowledge engineer combines and organizes the formalized knowledge to make it compatible with the information flow characteristics of the problem, resulting in a prototype that can be executed and tested.
- *Testing* - The performance of the prototype is evaluated and revised to conform to the standard defined by experts in the problem domain. Typically, this is an iterative process: an expert evaluates the program's performance, while the knowledge engineer revises the knowledge base.

It is beyond the scope of this paper to examine knowledge acquisition techniques in detail. Note that most of these techniques require that knowledge be elicited from information sources and first placed into an **information base**. From there, it is analyzed and organized into knowledge bases, and then used with an Expert System. The knowledge must be tested for *necessity and sufficiency*, and the knowledge bases must be refined accordingly. Techniques in knowledge acquisition often have roots in psychology: the Delphi technique[8] and Personal Construct Theory.[9] The interested reader is encouraged to examine

these and other sources of knowledge acquisition information.

Our PC/PROLOG based Expert System for tuning MVS/XA faced the same problem of knowledge engineering / knowledge acquisition. Though we chose as our initial knowledge source written material (e.g. papers, IBM manuals), we first addressed questions of identification. We felt that the most common types of tuning problems for MVS/XA are I/O related; thus, the class of problems for our first prototype was limited to I/O and paging/swapping. We next needed to identify the data that would be required, and this was inferred from our information sources. For example, we decided that it would be important to know whether or not dedicated page volumes were being used. Overall, the objective of our system was to gather information about the presence/absence of performance "symptoms", analyze these to form a "diagnosis", and then suggest a "treatment."

In defining the structure, we grouped certain traits together that are related to specific problems. For instance, values for pend time, connect time, disconnect time and IOS queue time are related to poor I/O response time - we could derive a value for I/O response time from these traits. The procedures for finding a problem could then be informally described by grouping the key traits together, inferring any additional information, and finally describing (informally) the relationships (rules) between the traits and the problems to be solved.

The formalization of structure into a more formal representation is usually made easy when an Expert System shell is used. The format of rules is specified by the shell, so the transformation does not have to be difficult. In our case, no such shell was used; our problem was compounded because we were developing our own shell. In a later section of the paper, we will describe the steps that were taken to build a shell and to determine a "language" for expressing CPE rules.

Implementation implies that the system be built. This process will be described later. But an interesting question about the focus of rules comes up. We might build a rule like "If page delay time is greater than 100 msec, then you should examine the page/swap dataset configuration." Here, the presence of the symptom (page delay time > 100 msec) implies a potential diagnosis, which would have a corresponding treatment (e.g. consider dedicated page volumes). We will call this a *forward leading predicate*. But now consider the following: if a treatment was "use dedicated page volumes", then couldn't the Expert System ask "are you using dedicated page volumes?" If the answer were yes, then suggesting this as a possible treatment is redundant and confusing. This is an example of a *backward looking predicate* - the presence of a potential treatment would imply that the Expert System should look for *other* treatments, or, reply that the system does not know a treatment for the problem.

Testing our prototype consists simply of letting an "expert" use the system, and incorporating any additional knowledge the expert gives into the system. For this, our prototype was given a "why" facility - the ability for the user to ask how a particular diagnosis was reached. In addition, the prototype was given an editing capability over the contents of the knowledge base. Using commonly used PC editing keys, the expert could **add, delete or modify** not only the rules in the system, but the control mechanism, and the contents of the help, diagnosis and treatment messages that the system uses. In short, the expert is given full control of all of the knowledge that the system has during the entire testing process. After testing, these features were left in the Expert System.

4. PROLOG

Over the past two decades, the price of hardware has dropped dramatically, while the costs associated with software development have now become the dominant portion of a total system budget. This rapid rise has influenced the development of new programming tools that simplify system development. PROLOG is the result of years of effort in this area. PROLOG was developed at the University of Marseilles, France by Alain Colmerauer in the early 1970's. It was designed to be a convenient tool for *PRO*gramming in *LOG*ic (hence the name). It can be more powerful and efficient than many traditional programming languages (e.g. PASCAL, FORTRAN, etc.)

A PROLOG program uses a description of a problems' facts and rules, and then finds all possible solutions to the problem. In PROLOG, a programmer describes *what* must be computed, rather than how the computation should be carried out. This declarative (rather than procedural) approach eliminates well known errors that are common in other programming languages (e.g. one too few iterations in a loop). So aside from some initial declarations, a PROLOG program consists of a set of *facts* (e.g. john likes mary, tom likes sam), and a set of *rules* (e.g. jean likes X if tom likes X). PROLOG *deduces* that jean likes sam. Goals like "find every person who likes sam" can be asked of a PROLOG program. PROLOG uses a built-in backtracking mechanism that, once one solution has been found, causes PROLOG to reevaluate any assumptions that were made to see if some new variable values will provide additional solutions.

To better understand the syntax and operation of PROLOG, consider the following sample program:

```
clauses
   watches(bill,bob).
   watches(john,jane).
   watches(fred,felicia).
   watches(mitch,bill).
   watches(brenda,greg).
   watches(bob,bob).
   watches(fred,greg).
   watches(bill,phillipe).
```

The clause "watches(bill,bob)" is the fact "bill watches bob." Thus, if we pose as a goal "watches(mitch,bill)", PROLOG would reply "true". "watches(bill,jane)" would result in a reply of "false". Variables begin with upper case characters; thus a goal of "watches(john,Who)" (analogous to asking Who does john watch?) causes a reply of "jane". But the goal of "watches(fred, Who)" results in **both** "greg" and "felicia". The "_" character is called the blank variable; a goal of "watches(fred,_)" is analogous to asking "does fred watch anyone?" This would result in the reply true.

If we add the *rule* "happy(eric) if watches(brenda,eric)" (i.e. eric is happy if brenda watches eric), the goal "happy(eric)" ("is eric happy") would be satisfied. The rule "nervous(Who) if watches(bill,Who)" would be satisfied with "bob" and "phillipe"; this is analogous to asking "Who is nervous", and answering using the rule "someone is nervous if bill is watching them." Thus, PROLOG looks through the already established facts and concludes that since bill watches both bob and phillipe, that both bob and phillipe are nervous.

Though there are many interesting features of the language (the reader is encouraged to examine the cut operator, as well as backtracking), the most commonly used *data structure* is known as a **list.** Analogous to arrays, lists are collections of objects (elements) of the same type, separated by commas and placed inside square brackets. For example, **[1, 2, 3]** is a list of the integers 1, 2, and 3. PROLOG can manipulate a list by dividing it into two parts: a *head* and a *tail.* The head is the first object on the left in the list; the tail is the rest of the list. Syntactically, a PROLOG list is written with a vertical bar separating the head from the tail **[head | tail]**. Lists are treated just like other objects in PROLOG, and PROLOG has built-in facilities (predicates) for manipulating the elements of a list.

5. The Development of the Expert System

The reader should, as this author did, feel comfortable with the concept of an Expert System, as well as some PROLOG basics. The discussion now turns to building the system itself. Consider that this author is (by definition) a programmer of *procedural* languages (FORTRAN, PL/I, C, etc.) Thus, PROLOG is somewhat unnatural, and causes some conceptual problems that have to be overcome. For example, consider the following rule: Bad I/O response time exists if pend time is greater than or equal to 10% of the sum of disconnect plus connect time, and IOS queue time is greater than the sum of pend time, disconnect time and connect time. In PROLOG,

```
bad_resp(IOSQ, PEND, DISC, CONN) if
   PEND > = (DISC + CONN) * 0.10  and
   IOSQ > (PEND + DISC + CONN).
```

This simple rule implies the our PROLOG program should:

- Prompt the user for the value of each variable (IOSQ, PEND, etc.),
- Provide help with each prompt should the user not understand what is being asked for,
- Validate each resulting reply - here, with a simple numeric test,
- Pass the replies as parameters to this rule that does the evaluation (bad_resp(IOSQ, PEND, DISC, CONN)),
- If the rule is satisfied, provide the user with the diagnosis (poor I/O response time because of these symptoms),
- Look up a treatment for this diagnosis.

Our first version of the system has the rule (knowledge) coded in PROLOG; thus it is part of the reasoning process. Given all the rules to be coded, plus the help, diagnosis and treatment messages, the resulting program was rather long, and strongly resembled a traditional procedural program.

Recall that an objective of an Expert System is to *separate* the knowledge from the reasoning process. Our first version mixed the knowledge and reasoning process together. Thus, we examined the rules a little closer, since they were the driving force behind the design of the program. When invoked, rules result in true or false. Thus, if the prompts were structured as true or false

questions, the inference mechanism could be greatly simplified. For example, consider the following:

```
demand_paging_problem(P1, P2) if
  ask(i1, P1) and
  ask(i2, P2).

ask(Index, Prompt) if
  prompt(Index, Prompt) and
  write("Is ",Prompt,"? ") and   /* an ordinary write   */
  readln(Reply) and              /* read the user reply */
  yes(Reply).                    /* validate the reply  */

prompt(i1,"Demand Paging High").
prompt(i2,"storage isolation used for IMS or CICS").
```

The inference mechanism "ask" is now divorced from the knowledge of what prompts should be used. The prompts themselves are associated with specific *traits* (i1, i2). For illustration, we have included the prompt clauses within the program, but the collection of prompt clauses is ordinarily kept within a *separate, editable file.*

Note though that the control information - ask about trait i1 then trait i2 relative to demand paging - is still part of the PROLOG program. Thus, we need to carry this "separation" of knowledge from reasoning one step further. We create in a separate, editable file, a **knowledge base** of the following form:

- prompt(trait, prompt messages).
- condition(symptom, [list of traits]).
- diagnosis(symptom, [list of traits], treatment).
- treatmsg(treatment, treatment messages).
- diagmsg (treatment, diagnosis messages).
- helpmsg (trait, help messages).

where:

- *prompt* - associates with each trait the corresponding prompt message to ask the user. "Is" is printed before each prompt message implying a true/false question.
- *condition* - associates a list of traits with a particular symptom. For example, condition(ratehi, [i1, i2, i3]) would imply that traits i1, i2 and i3 are all associated with the symptom ratehi. This knowledge is used to *control* the flow of prompting.
- *diagnosis* - associates the true/false values of traits with whether a particular symptom exists. If the symptom does exist, *treatment* is the index to invoking the correct diagnosis and treatment messages. For example, consider
  - diagnosis(ratehi, [i1, i3], fixrate).
  - prompt(i1, "Demand Paging High").
  - prompt(i3, "Storage Isolation Used for IMS or CICS").

  This implies that the condition ratehi is present if traits i1 and i3 are both true - demand paging is high and storage isolation is being used for either IMS or CICS. A minus sign "-" in front of a trait, e.g. -i2, would imply that trait i2 is tested for falsehood. On closer examination, *diagnosis* represents how tuning rules are coded. If it is possible for a symptom to be caused several different ways, then each possibility can be coded; the inference mechanism automatically checks for all possible solutions.
- *treatmsg, diagmsg* - associate a treatment with a set of messages - treatmsg deals with treatments, diagmsg deals with diagnoses.
- *helpmsg* - associates a trait with a set of help messages that try to give more information about the particular trait.

Thus, each of the above represents knowledge, and is kept in a file that can be edited by the user. The inferencing mechanism is thus reduced to processing these predicates; it is short, and contains no knowledge. Conceptually, it can be used in any expert application as long as the syntax outlined above is followed.

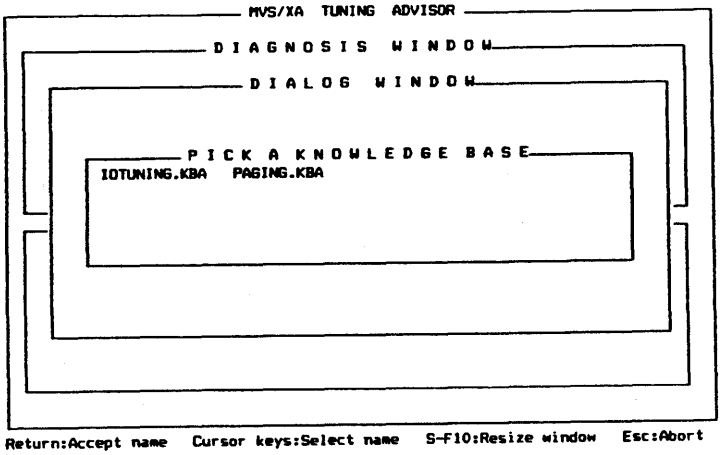
Several features were added to the general inferencing mechanism: after a consultation, the user can invoke a built-in editor, which resembles the PC word processing program WORDSTAR.[10] Rules can be added, deleted or modified. Care should be taken so as not to violate the syntax outlined above - no syntax checking is done. In addition, a "Why?" feature was added. After each diagnosis is given, the user is given the opportunity to ask the Expert System why that diagnosis is being given; in other words, how that conclusion was reached. The inferencing mechanism *backtracks* from the treatment using the diagnosis and prompt predicates to replay the rules that were invoked using English.

6. A Consultation Session

It is difficult for the reader to get a firm understanding of the Expert System described unless (s)he has the actual floppy disk with the program available. To eliminate this difficulty, this section will display parts of a sample consultation session with the Expert System. The discussion will show the screen displays a user would see, and will provide an overview of the overall flow of the system. Finally, we will give a short discussion of how a knowledge base can be edited.

Required Files - First, the program (henceforth called *ADVISOR*) must be present along with at least one knowledge base. Knowledge bases are ordinary text files that can be created by any ordinary PC editor that does not use embedded control characters. *ADVISOR* knows that files are knowledge bases if they end with the suffix KBA (for *K*nowledge *BA*se). In our prototype, we created two knowledge bases, IOTUNING and PAGING.

The following is what is displayed when *ADVISOR* is invoked:



The user uses the PC arrow keys to select which knowledge base they want to use; in essence, this is actually equivalent to selecting a *knowledge domain* to be exploited.

At this point, we point out the different *windows* that *ADVISOR* uses.

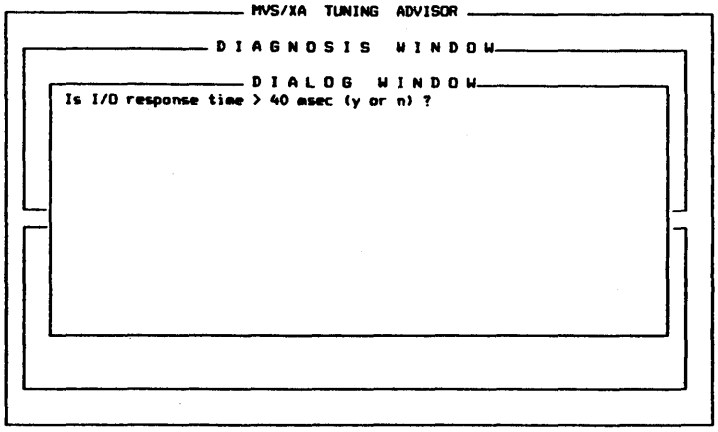
- *DIALOG* - This window is the primary means of communication between *ADVISOR* and the user. Performance questions are posed to the user, and each reply should be followed by hitting the RETURN key.
- *HELP* - Should a user need assistance in understanding a question, the HELP window will display that information. HELP is invoked by replying with a ? to the question posed in the DIALOG window. In addition, the HELP window is used later to explain why a particular diagnosis was arrived at.
- *DIAGNOSIS* - After a set of related performance questions is asked, any performance problem found will be noted in the DIAGNOSIS window. Here, the user is given the opportunity of asking why a particular DIAGNOSIS is being made.

---

10. WORDSTAR is a registered trademark and product of the MicroPro International Corp.

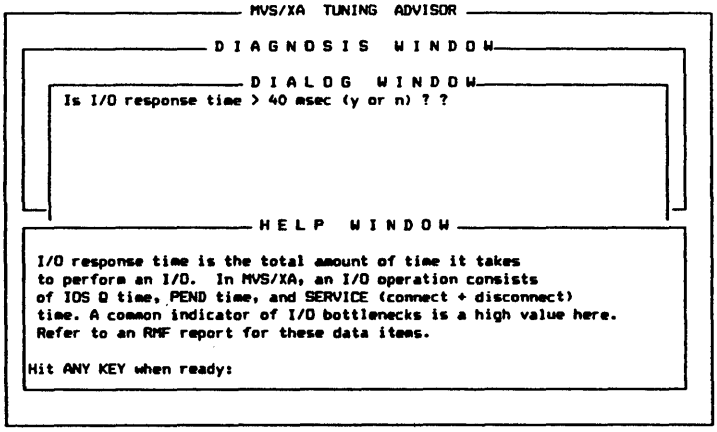
- *TREATMENT* - Often, a particular diagnosis will have one or more possible remedies, or TREATMENTS. Each possible TREATMENT is displayed in this window successively, each one being preceeded by giving the user the opportunity to ask WHY.
- *EDIT* - Once a consultation session has ended, the user is given the opportunity to edit a knowledge base. Here, a *full-screen* editor is invoked that allows the rules in the knowledge base to be modified, deleted or extended.

We now examine several screens to become familiar with the "look and feel" of the system. As each question is asked in the DIALOG window -



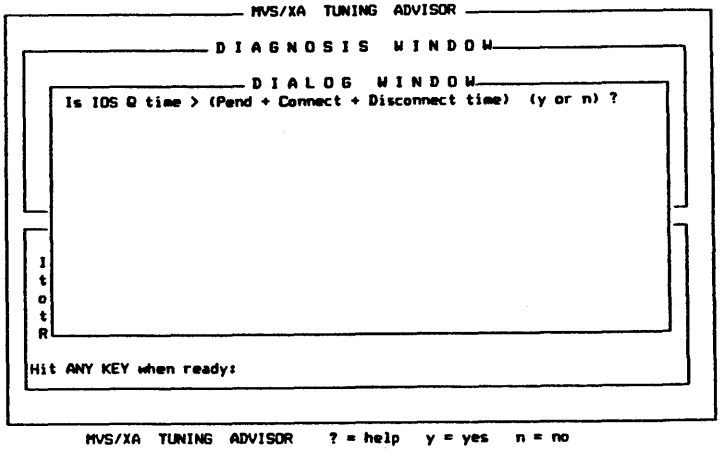
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
DIALOG WINDOW
Is I/O response time > 40 msec (y or n) ?
MVS/XA TUNING ADVISOR ? = help y = yes n = no

the user can ask for help by typing ? and hitting the return key -



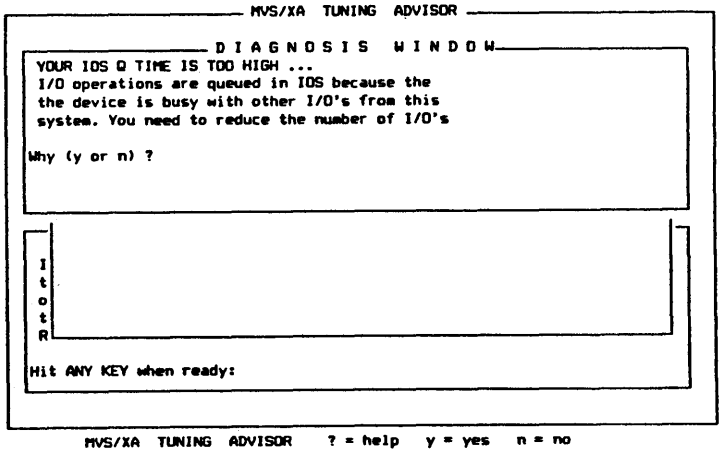
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
DIALOG WINDOW
Is I/O response time > 40 msec (y or n) ? ?
HELP WINDOW
I/O response time is the total amount of time it takes
to perform an I/O. In MVS/XA, an I/O operation consists
of IOS Q time, PEND time, and SERVICE (connect + disconnect)
time. A common indicator of I/O bottlenecks is a high value here.
Refer to an RMF report for these data items.
Hit ANY KEY when ready:
MVS/XA TUNING ADVISOR ? = help y = yes n = no

When finished with help, typing any key will return the user to the DIALOG window, where (s)he is reminded to reply with a *y* (yes) or an *n* (no). From there, the next question is asked -



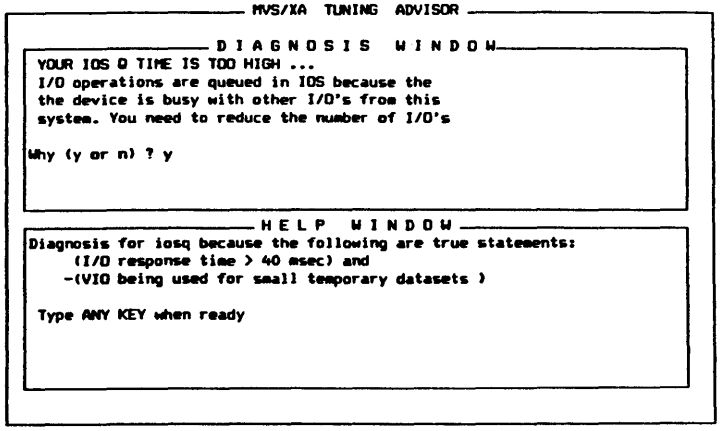
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
DIALOG WINDOW
Is IOS Q time > (Pend + Connect + Disconnect time) (y or n) ?
Hit ANY KEY when ready:
MVS/XA TUNING ADVISOR ? = help y = yes n = no

Once all of the questions or *traits* corresponding to a logical sequence have been asked, descriptions of any performance problems detected appear in the DIAGNOSIS window -



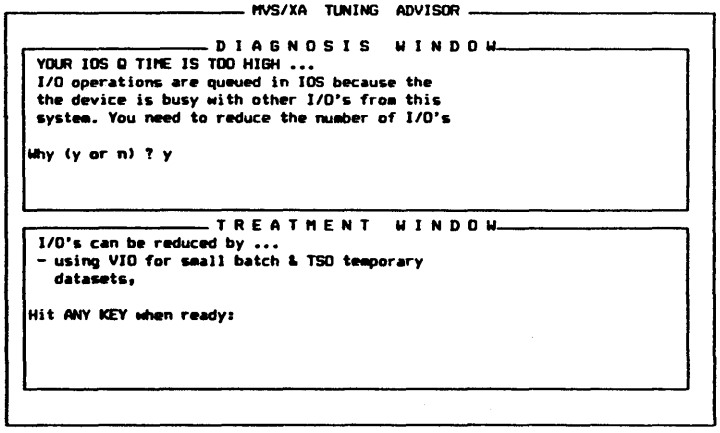
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
YOUR IOS Q TIME IS TOO HIGH ...
I/O operations are queued in IOS because the
the device is busy with other I/O's from this
system. You need to reduce the number of I/O's
Why (y or n) ?
Hit ANY KEY when ready:
MVS/XA TUNING ADVISOR ? = help y = yes n = no

Here, the user is given the opportunity to ask what caused (WHY) this diagnosis to be made by *ADVISOR*. If the user replies *n* to the WHY prompt, the TREATMENT window appears (more later). If the user replies *y* to the WHY prompt, the HELP window reappears containing an English-like replay of the prompts used to arrive at the current diagnosis -



MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
YOUR IOS Q TIME IS TOO HIGH ...
I/O operations are queued in IOS because the
the device is busy with other I/O's from this
system. You need to reduce the number of I/O's
Why (y or n) ? y
HELP WINDOW
Diagnosis for iosq because the following are true statements:
(I/O response time > 40 msec) and
-(VIO being used for small temporary datasets)
Type ANY KEY when ready
MVS/XA TUNING ADVISOR ? = help y = yes n = no

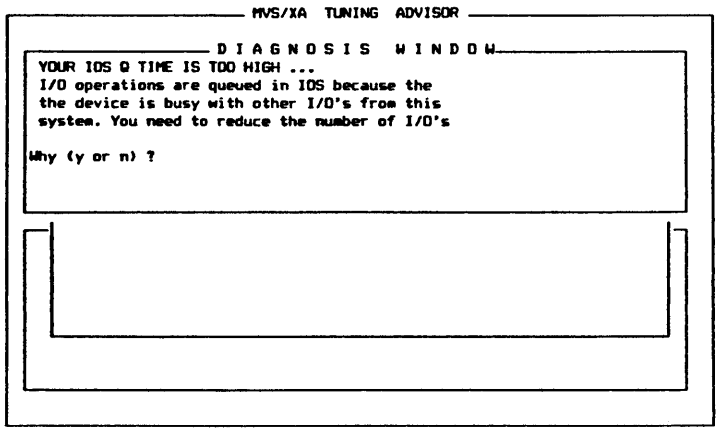
Notice, if a particular prompt is preceeded with a hyphen (-), this implies the *negation* of the particular prompt. Next, the user types any key which causes the HELP window to be replaced by the TREATMENT window. Here, a possible suggestion is made that the user can adopt to ultimately help tune the actual MVS system.



MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
YOUR IOS Q TIME IS TOO HIGH ...
I/O operations are queued in IOS because the
the device is busy with other I/O's from this
system. You need to reduce the number of I/O's
Why (y or n) ? y
TREATMENT WINDOW
I/O's can be reduced by ...
- using VIO for small batch & TSO temporary
datasets,
Hit ANY KEY when ready:
MVS/XA TUNING ADVISOR ? = help y = yes n = no

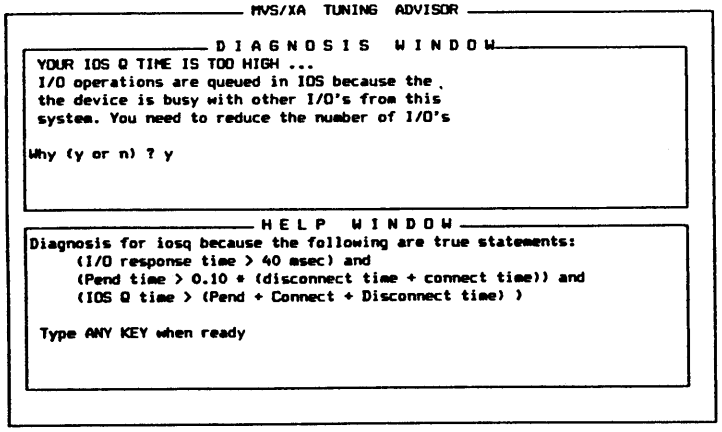
As before, the user types any key which causes *ADVISOR* to continue.

If a particular diagnosis reappears following the disappearance of the TREATMENT window,



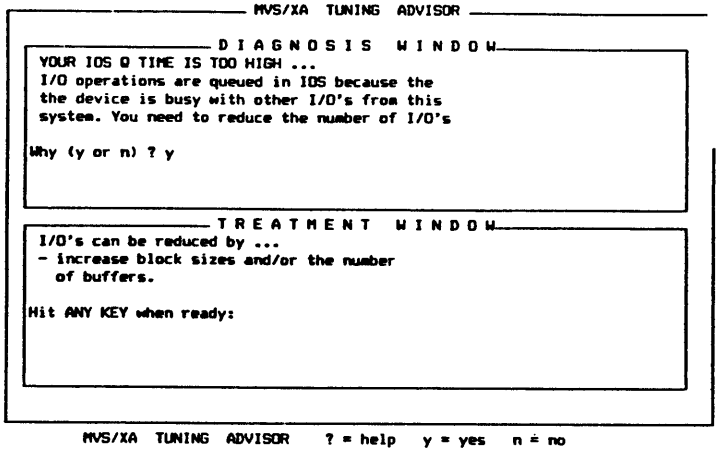
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
YOUR IOS Q TIME IS TOO HIGH ...
I/O operations are queued in IOS because the
the device is busy with other I/O's from this
system. You need to reduce the number of I/O's
Why (y or n) ?
MVS/XA TUNING ADVISOR ? = help y = yes n = no

it implies that the current diagnosis has been reached by invoking additional rules. Again, the user can ask WHY, and we can see that a different reply is given in the HELP window.



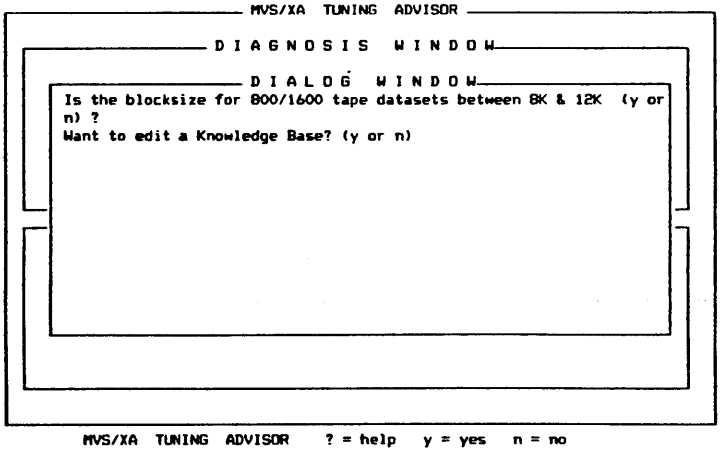
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
YOUR IOS Q TIME IS TOO HIGH ...
I/O operations are queued in IOS because the
the device is busy with other I/O's from this
system. You need to reduce the number of I/O's
Why (y or n) ? y
HELP WINDOW
Diagnosis for iosq because the following are true statements:
(I/O response time > 40 msec) and
(Pend time > 0.10 * (disconnect time + connect time)) and
(IOS Q time > (Pend + Connect + Disconnect time))
Type ANY KEY when ready
MVS/XA TUNING ADVISOR ? = help y = yes n = no

And, as before, the HELP window is replaced by the TREATMENT window, this time giving a *different* remedy the user might apply to the actual MVS system.



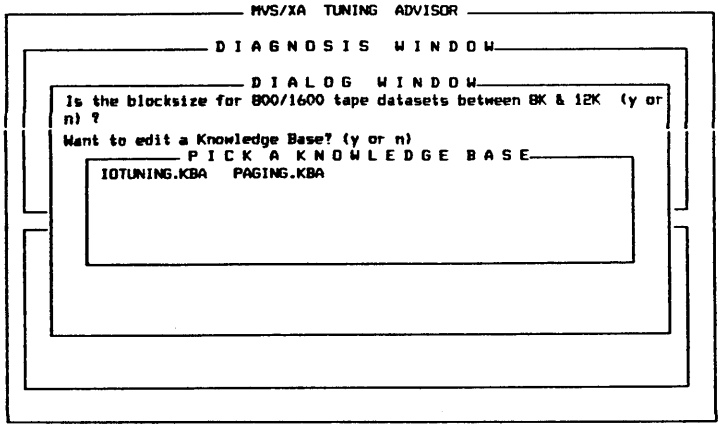
MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
YOUR IOS Q TIME IS TOO HIGH ...
I/O operations are queued in IOS because the
the device is busy with other I/O's from this
system. You need to reduce the number of I/O's
Why (y or n) ? y
TREATMENT WINDOW
I/O's can be reduced by ...
- increase block sizes and/or the number
of buffers.
Hit ANY KEY when ready:
MVS/XA TUNING ADVISOR ? = help y = yes n = no

Once the consultation session has ended, the user is given the opportunity to edit a knowledge base - (a no reply ends the session).



MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
DIALOG WINDOW
Is the blocksize for 800/1600 tape datasets between 8K & 12K (y or n) ?
Want to edit a Knowledge Base? (y or n)
MVS/XA TUNING ADVISOR ? = help y = yes n = no

As at the start of program execution, the user selects a knowledge base with the PC arrow keys followed by enter. Here, a full-screen editor similar to WORDSTAR is invoked that operates on the knowledge base.



MVS/XA TUNING ADVISOR
DIAGNOSIS WINDOW
DIALOG WINDOW
Is the blocksize for 800/1600 tape datasets between 8K & 12K (y or n) ?
Want to edit a Knowledge Base? (y or n)

7. Issues for Future Development

As this PC/PROLOG based system is still in its infancy, several issues regarding where the system should next go need to be expressed. The following issues should apply to any Expert System for CPE.

1. *Location Help* - Rather than just explaining the meaning of traits in help messages, add information about where to find measurement(s) associated with the trait; e.g. on page 2, bottom of an RMF report. This is an example of using an additional class of knowledge that, until now, only the expert has.
2. *Automatic Data Reduction* - Ideally, a "front-end" mechanism that could read and analyze measurement sources like RMF automatically would greatly simplify the user's interaction with the system. Rather than putting the burden of responsibility on the user to get the answers to the prompts, a program(s) could be designed to extract the corresponding answers, and download these to the PC. A potential source for much of this data could be the MICS data base (Morino Associates), which is a repository for many different types of measurements. The MICS data dictionary already assigns names to many measurements, and these names could be related to the traits we referred to previously.
3. *Links to other PC packages* - If data were downloaded from the mainframe to the PC, it could be stored in a spreadsheet or a database. Products like 1-2-3 from Lotus Development or dBASE-III from Ashton-Tate could then be used to do the analysis on the PC rather than the mainframe. These could be invoked from PROLOG directly, as the interface is already defined.
4. *Certainty Values* - As Artis pointed out (5), some rules are not as clear cut as one would like. If a certainty value, say between 0 and 100, was attached to each rules' conclusion, a *certainty threshold* could be specified for the premises. Below this threshold, rules are considered to be false. This would allow *fuzzy reasoning* to be a part of the system.
5. *External Program Execution* - As in many mainframe offerings, it is sometimes convenient to have an **exit** facility. This would allow the PROLOG system to escape to execute some user-specified program, and then return. This could greatly increase the potential applicability of the system.

8. Conclusions

The objective of this paper was to provide new insight into CPE by applying AI techniques. An Expert System is a complicated object with many advantages; foremost among these is that expert knowledge is elicited and stored in an executable form.

The system described is only a beginning at applying current technology. It was **never intended** to replace the human expert. On the contrary, the original intent was to use the system as a training mechanism, where a new CPE practitioner could pose performance scenarios to the Expert System, and see how these would be analyzed, and what recommendations would be made.

It is our belief that similar applications will flourish in the next decade. Yet, though the size of knowledge bases may increase, we believe that the human inference mechanism is still better than any that will be built during that time. We conclude with the following from Aristotle: "It is the mark of an instructed mind to rest satisfied with the degree of precision which the nature of the subject admits, and not to seek exactness when only an approximation of the truth is possible."

9. Acknowledgements

The author would like to take this opportunity to thank those referees and Editorial Review board members of the Computer Measurement Group for their constructive comments and suggestions. In addition, we would like to thank Bell Communications Research for the opportunity to explore this area. In particular, the members of Bellcore's Performance Management District served as a *set* of experts from which the Expert System was examined. Their input is gratefully appreciated.

A Flexible Approach to Performance Prediction For Large System Software Development

by A. Long and W. Suhler
IBM Corporation

ABSTRACT

Assessing large system software performance is a difficult task at best. When much of the system's software is still being designed and coded, the rapidly changing environment of the project increases the difficulty of the assessment task. In this situation a performance evaluation system must have the capability to meet the wide-ranging demands for performance analysis and the flexibility to handle the "moving target" nature of the software. This paper describes how one performance evaluation system was developed by IBM Federal Systems Division to meet these needs. This system consists of a data base, a simulator, and an analytical model that also serves as a pre-processor to the simulator. The paper also describes the flexible features of each of these parts and provides illustrations of their use.[1]

1. INTRODUCTION

This paper describes a performance evaluation approach to quantify the performance of large, customized systems. The approach consists of a set of procedures and flexible tools used together to analyze performance throughout the system life cycle.

This general methodology evolved over the multi-year cycle of one complex, customized system. As development proceeded from preliminary design through coding and testing, a number of tools were developed and/or used to predict the expected performance of the operational system. The performance products ranged from pure estimation of system performance, to system measurement, and to modification analysis.

This paper is an expansion of an earlier paper [1], which reported an initial approach to estimation of stand alone timings. Because of the proprietary nature of the projects to which this performance effort was directed, a hypothetical example [Section 4. Example Development Effort (Library Automation Project)] has been included. Actual library data was used to calibrate the required model input data.

1.1. PERFORMANCE PROBLEM

This method addresses the problem faced by all large development efforts: the reduction of risk by the earliest possible identification of performance problems. Performance cannot easily be grafted onto a system in its final development stages, and any attempt to do so is expensive. Since early discovery of flaws can lower the cost of fixes by orders of magnitude, we needed to provide the earliest possible prediction, tracking, and analysis of system performance.

1.2. PERFORMANCE EVALUATION EFFORT

The performance effort described in this paper is divided into discussions of:

- The general performance approach to performance analysis of a large development project,
- Our specific implementation, and
- Our approach applied to a sample project.

2. DEVELOPMENT PROJECT FROM A PERFORMANCE VIEWPOINT

2.1. PROJECT LIFE CYCLE

The nature of performance analysis changes as a project proceeds through its life cycle with the requirement that the performance analyst play an integrated role throughout. Historically, the role of the performance analyst has usually been that of a late arrival resulting in limited impact on the project. The preferred role has performance directly involved with the development process from the outset. This permits performance to play a significant role in the direction of the development effort. Ferrari emphasizes this role in a recent IEEE article [2]:

> "... The performance evaluation viewpoint ... does not favor serendipity as the ordinary approach to (performance) problem solving, 'hacking,' or 'hack now, fix later' methodology."

2.1.1. PROJECT OUTSET (Design for Performance). The goals of the performance analyst at the project outset are:

- To identify critical performance parameters,
- To make initial estimates of these parameters, and
- To assist in the solution of problems identified by the initial estimates.

At the project outset, software architects will be assessing and modifying candidate designs at an amazing rate. The performance analyst must keep up with these furiously changing designs and, additionally, provide insight into their performance ramifications. To provide some method for this madness, the analyst must quickly focus on a method of quantifying performance and stick with it.

There are many candidate performance measures for system tracking (e.g., CPU utilization, transaction throughput, response time, system availability, required floor space, power). The trick is to identify an appropriate subset that will permit the practical tracking of project technical performance (current and future) through all system development phases.
One tracking methodology is presented in MIL-STD-499A [3]. This document describes how these Technical Performance Measures (TPMs) are selected, reported, and

---

[1]Permission is granted to CMG to publish this paper in its publications. IBM retains the right to publish this paper elsewhere or distribute copies of it to whomever it chooses.

utilized. The basic idea with TPMs is to reduce the performance tracking to a workable level (both from a resource and a management viewpoint) while accurately representing overall system performance. All of the performance values will be estimates at the project outset (but system improvements can be made at very low cost). The disadvantage of these early estimates is they rely on marginal input data. Some of the different inputs that must be estimated are:

- o Software characteristics (e.g., application path lengths),
- o Machine characteristics (e.g., internal throughput ratios),
- o Operator characteristics (e.g., time to perform various tasks at interactive screens), and
- o Environmental characteristics (e.g., impacts of the operating system or other applications).

2.1.2. PROJECT MIDCOURSE (Development with Performance Corrections). The goals of the midcourse effort are:

- o To advise management of performance problems as they are detected,
- o To keep the performance improvement process focused, and
- o To provide assistance for test plan generation.

After the initial designs are complete, the performance analyst must keep the performance effort focused as the code is written. Changes and problems will continue to surface, and, inevitably, management will not have sufficient resources to deal with all of them immediately. The analyst must identify the "Heavy Hitters" among the problems and advise management of the best application of its resources.

At a project's midcourse the measurement of actual code performance becomes possible. This measurement provides, at a high level, information on such items as task elapsed and CPU timings and at a lower level, individual subtask timings and I/O activity. The cost of making corrections to the code at this point is still considerably cheaper than after the code becomes operational. Caution in the use of the absolute value of measurement results is necessary at this midcourse because the applications and system software are untuned and will produce timing values orders of magnitude larger than the estimates initially generated and the expected results after system tuning.

2.1.3 PROJECT OPERATIONS (PERFORMANCE ENHANCEMENT). The performance goals of project operations are:

- o To understand and quantify how the system is actually used,
- o To maintain workload projections, and
- o To plan for system enhancement.

After the system becomes operational, the performance analyst is the focal point for analyzing changes to the system. The analyst must keep a current model of the system which can be used to study varying conditions and to plan for increasing workload.

When the system becomes operational the tuning will have been completed and the environment will have become realistic. Now, however, the cost of performance enhancements will have increased several orders of magnitude. The focus of performance will have shifted towards future growth through system upgrades and enhancements.

2.2 TOOLS NEEDED

The tools needed to quantify TPMs vary over the project development cycle. The tools fall into three categories:

- o Tracking,
- o Estimation, and
- o Measurement.

2.2.1 TRACKING TOOLS. A large application will always have many tasks and details associated with it. To keep track of these items for a performance effort, a data base must be employed. In the early design phase, the data base is used to keep track of the hierarchy of tasks being developed. As task data (requirements, model estimates, and measurements) becomes available, they can be stored in the data base as a central collection and communication point. Periodic and ad hoc reports can be prepared from the data base.

2.2.2. ESTIMATION TOOLS. The performance analyst needs some way of obtaining early TPM estimates. These estimation tools generally come in two flavors: analytical models and simulations. Analytical models, by expressing the operation of the system in mathematical terms, provide a quick picture of stand-alone performance. They can provide as much (or as little) detail as is required and can be tailored to the particular TPMs of interest. Simulations permit a more customized representation of a system, but require more effort. The two tool types complement one another.

2.2.3. MEASUREMENT TOOLS. Measurement of task performance first becomes feasible during early testing, and can be performed in a number of ways. The operating system will provide standard accounting capabilities that can be used to calculate some performance parameters. In addition, specialized performance software is available from a number of vendors to augment the data supplied by the accounting tools. Both sets of tools are useful when applied together, but the data must be correlated. In addition, measurement data can be used to verify the estimation results and to improve the accuracy of the inputs to the estimation tools.

3. OUR SPECIFIC APPROACH

3.1 OUR PROJECT LIFE CYCLE

Our project covered several years during its multi-phase development. We worked in parallel with the project developers through two groups. The first, the Performance Working Group, was formed to explore the technical issues behind performance problems. The second, the Heavy Hitters Group, was formed to provide a management focus to the performance work.
In the early design phases estimates of run duration were provided and bottlenecks were identified. As the project moved to coding and testing, this parallel work continued and expanded to include collection of measurements. Care was taken to gather data as "targets-of-opportunity" became available to minimize additional test workload. As measurements were gathered during functional testing, results were analyzed to determine whether performance was within appropriate bounds.

When early measurements indicated potential performance problems, the code was examined for "quick-fix" problems (e.g., problems with parameter settings or data base access choices which could be corrected without changing

source code). Any problems of this category were fixed and functional testing continued.

If these measurements indicated that a task still would not meet operational performance requirements, then the task code was moved to a performance testbed and analyzed further. There the Performance Working Group ran instrumentation to isolate performance problems and assist in evaluation of suggested solutions.

3.2. OUR TOOLS

The specific tools chosen for our project were a collection of standard commercial packages and locally produced code.

3.2.1. TRACKING TOOLS. The performance data base was developed in PC FILE III [5] to provide for the easy retention of the collected task timeline information. Task characteristics included parameters such as I/O activity volume and type (e.g., random fetch, sequential update); CPU cycles at task start, midcourse, and task end; and test measurements. These characteristics were upgraded from rough estimates during preliminary design phase to tuned measurements as the code moved through the development process.

3.2.2. ESTIMATION TOOLS.

3.2.2.1. Analytical Summary Model. Four user defined parts compose the analytical summary model:

- o A set of variables describing software, hardware, operator, and environmental characteristics;
- o A set of equations describing resource requirements for each defined subtask;
- o A list of all other subtasks called by a given subtask and the quantity of these calls; and
- o A recursive algorithm that combines the variables and the equations to represent the structure of the actual code.

Further discussion of this analytical structure can be found in [1]. The outputs of these models were retained in the performance data base.

3.2.2.2. Discrete Simulation Contention Model. A discrete simulation model was developed to study system operation under a variety of timeline scenarios. This simulator, coded in PL/I [8] with imbedded GPSS macros [9], represents the baseline configuration illustrated in Figure 1. It includes a CPU, strings of Direct Access Storage Devices (DASD), controllers, and operators. These resources appear generically in the simulator code. A set of input files is superimposed on this baseline to define the specific operational system being simulated.

3.2.2.2.1. Inputs. Three types of input files are used by the simulator: a system characteristics definition, an applications software description, and a scenario description. The system characteristics definition includes hardware specifications (such as processing power and average DASD access rate) and system software specifications (such as operating system overhead). In this description the task may be treated as a single entity (e.g., CPU processing) or it may be decomposed into hundreds of steps with a description of the resources needed for each.. The scenario description lists application software tasks run during the simulation and the start time of each. The application software description lists the resources needed by each task. The analytical model produces this description as one of its outputs.

3.2.2.2.2. Processing. The simulation permits multiple strings of tasks to contend with one another for limited system resources.

3.2.2.2.3. Outputs. The model provides its results in two forms: the standard GPSS reports and the timeline reports generated in the PL/I code. The standard reports give a variety of statistics on resource use including number of service requests per resource, average service time per request, and average queuing time. The timeline report lists the start, end, and duration of each task.

3.3. OUR MEASUREMENT TOOLS

Standard monitors such as RMFMON [6] and OMEGAMON [7, Note: OMEGAMON is a trademark of the Candle Corporation] are used to obtain such measures as task CPU, I/O, and elapsed times. These measurements are retained in the performance data base. These results provide insight into potential performance problems and performance tuning progress.

4. EXAMPLE DEVELOPMENT EFFORT (LIBRARY AUTOMATION PROJECT)

4.1. SYSTEM OVERVIEW

We have chosen a library automation package to illustrate how these tools are used for software development. The example library system handles a variety of tracking and inventory functions for a regional library in a large county system. Per region the system has approximately 100,000 patrons and 200,000 volumes. A uniprocessor with DASD, library work stations with bar code wands, and conventional terminals was selected to service these functions (Figure 1).

4.2. FUNCTION TO BE ANALYZED

The timeline of interest for this example is the crux of the system: the patron's service function. This timeline is illustrated in Figure 2 - Technical Performance Measures (TPM) Budgets. The figure shows the types of data kept in the timeline data base. Each portion of the timeline is given a specified budget and an average data base size for which the budget applies. For this patron service procedure the timeline is broken into three sequential tasks: a patron status check, a checkout/return activity, and a statistical data update. For this example we will focus on the evolution of the checkout/return task. This task was deemed most critical and most difficult to perform within the required time constraints. A high-level flow design of this task is given in Figure 3 - Checkout/Return Task Flow Chart. The librarian initiates the checkout/return processing and proceeds through the task as described below.

4.2.1. Checkout/Return Initialization. After patron status check is complete, checkout/return initialization is invoked and information on overdue books, unpaid fines, and total books checked out is passed to the task.

Initialization includes locking the patron's record and establishing a checkout/return workspace.

4.2.2. Borrow Sequence. If the librarian selects the borrow sequence, he/she next reads in a book identification code. If the book is a reserve, the patron's request in the reserve list is cleared. The patron and the volume files are then updated as appropriate. The librarian may loop back through this procedure. When this sequence is complete, the statistical data update task is invoked to complete the patron's service function.

4.2.3. Return Sequence. If the librarian selects the return sequence, he/she reads in the book identification code, and the patron and volume files are updated. If the book is on the reserve list, the librarian will receive a message to hold the book. If the book is overdue, the fine is calculated and displayed. The librarian may also loop back through this procedure, and the total fine (if any) will be accumulated. When this sequence is complete, the statistical data update task is invoked to complete the patron's service function.

4.3. APPROACH APPLICATION

As the code proceeds through its life cycle the models are exercised in several ways to assist in project development and maintenance. Three examples of its utility are given.

4.3.1. Early Design Phase. For modeling purposes the code was described as in Section 3.2. The initial versions of these files are given in Figures 4 through 6. The working constants are listed in Figure 4. Figure 4 exhibits the values assigned to the variables, used in the procedure definition in Figure 5 (Checkout/Return Task Definition) and the call sequence in Figure 6 (Checkout/Return Call Sequence). Running the model with these inputs produced the report given in Figure 7 (Model Output).

This initial report highlighted a problem in both the borrow and return checks. A bottleneck at disk 4 caused the elapsed task time (147.6 minutes) to exceed its 9 second budget. This problem prompted the performance working group to analyze the design further and uncovered the reason for the problem, the implementation of the reserved list data base. The reservation information had been added to the patron file, requiring that on the average, half of the patron file be checked before a book's reservation status could be determined. The design was updated by moving this information to the volume data base and adding a pointer to patron information. The affected task definition equations were updated (Figure 8), and the model was run again reducing the run time to under 8 seconds.
Studying the design under contention next, all five operators were simulated simultaneously. With the baseline processor speed of 2.4 MIPs produced Contention Run 3.A. A second processor with a speed of 3.6 MIPs produced Contention Run 3.B. These runs show the additional compute speed did not accomplish much because the operators were the limiting resource.

4.3.2. Midcourse Development Use. As the code was generated initial measurements were made by the testers. These measurements exhibited values several times larger than the required response times. This is an expected result given the untuned state of the system. The measurement data provided model input which was used to generate a first curve (Figure 9, Line #1).

The performance fixes at this point are typically easy to locate and not too expensive to fix in terms of time and code change (e.g. data file placement, data transfer blocking factors, search algorithms). Some of these changes were then placed in the computer model and predicted improvements were obtained, Figure 9, Line #2. The results of these quick fixes were implemented in the prototype subsystem. Retesting indicated that the predictions were correct.

At this stage the results still did not exhibit either in the model or in the "piggybacked" tests the desired 9 second response over a sufficient range of terminals. A task force composed of performance working group members and system development personnel was established. The task force conducted controlled tests and analyses to identify where the remaining performance problems lay. Additional tuning improvements to the task were implemented in the system. Measurements were taken and these result appear in Figure 9, Line #3.

Testbed measurements were placed in the model and modified to reflect final tuning of the system. The model results indicated that the system should be able to meet the stated budgets at system installation. These results are exhibited as Figure 9, Line #4.

4.3.3. Operational Performance Use. In the development phase, model prediction was used to quantify performance. As the development cycle progressed, emphasis shifted to measurement, and by completion of the development essentially all results were based on measurement. The simulation capability, however, continued to play a direct role in predicting the need for future software and hardware enhancements.

The contention modeling capabilities of the simulator were used to evaluate the processor configuration required to meet an increased workload demand. A specific configuration with a specified processing capability, memory size and DASD size was selected. The model was used to determine whether the proposed configuration could handle the upgraded load of seven terminals. The checkout/return task was run in the simulation with 7 operators handling a peak period influx of patrons. The simulated elapsed time for the checkout/return task was 8.3 seconds. The CPU was 15% busy, a low value; however, the channel loading of 18% indicated a probable system maximum of 10 operators performing the checkout/return task.

5. APPROACH ADVANTAGES SUMMARY

Our experience has shown the approach provided valuable project support. It accurately identified problem areas and directly assisted in their resolution with minimal schedule impact.
This approach includes a number of features which make life easier for the performance analyst. It has the flexibility to work with whatever information is available. Tasks can be modeled in great or limited detail depending on what is known or what level of detail suffices to answer a given question. Tasks can be modeled singly to determine isolated run times or in groups to simulate contention for limited system resources. The modeling tools remain useful over the entire life cycle. As measurement data becomes available or requirements change, they can be folded into existing models. These features significantly increase the effectiveness of the performance analyst throughout the system life cycle.

There is, however, a threshold of project size and/ or complexity to cross before this approach becomes feasible. Any size project would benefit from the application of parts of the approach (within budget constraints). Because of the start-up costs of implementation, the application of the complete approach requires the financial coverage of a large project (producing several hundred thousand lines of code and spanning several years of development).

SIZING NEW AUTOMATED SYSTEMS HAVING UNKNOWN WORKLOADS: A STRUCTURED APPROACH

John L. Gibson
Federal Computer Performance Evaluation and Simulation Center

ABSTRACT

At some point, every business identifies new applications requiring automation. Two critical issues affect the costs of automation: defining the workload to be automated and estimating the required computer resources.

This paper presents a structured approach for projecting the hardware requirements to support new applications. Four steps were used in this approach: (1) workload definition in Natural Business Units (NBU's); (2) NBU translation to data processing workload units; (3) workload volume estimation; and (4) resource requirements estimation. This approach is practical for business environments of any size and with varying automation requirements.

1. INTRODUCTION

Capacity management is becoming a means of existence for Federal government data centers these days. The objective is classic: ensuring data centers provide adequate service to users today, tomorrow, next year, ad infinitum. Yet, long hardware and software procurement cycles, budget constraints, administration fluctuations, political maneuvering: all of these issues and more contribute to Federal data processing capacity illnesses that are only treated and never cured. Life for the capacity planner is pretty frustrating!

Occasionally, though, a slightly different capacity question appears to spur one's creativity and interest. This paper describes one such question: sizing systems for unknown workloads. The Federal Computer Performance Evaluation and Simulation Center (FEDSIM) was recently asked by a major government agency to address this issue.

Sizing systems for unknown workloads may seem to pattern the proverbial "chicken before the egg" scenario. Therefore, some additional background is presented below in three parts: (1) a statement of the problem; (2) a preliminary strategy; and (3) some of the risks identified early in the project.

1.1 THE PROBLEM

Suppose you have been given the responsibility for automating a manual process that represents a fundamental portion of your business. During an initial presentation to corporate management, you focus on the potential advances in productivity, enhancements to information accessibility and timeliness, and improvements to business scheduling and process control--all resulting from your automation plan. Suddenly, from the back comes a simple, but fair, observation: "I like the concept, but what are the hardware requirements?" Since your objective at this point was only to sell the automation plan, you may not have a definitive answer. But, your management expects the results from both sides of a cost/benefit analysis. Your next task has been clearly identified.

Determining the size of new automated systems is a complex problem that presents new challenges to the capacity planner. Typically, the capacity planner is concerned with future resource requirements based on workload forecasting and trending. Historical data are the basis for analyses and projections. For new systems, however, no historical perspective exists. The application design, the user community, and the service requirements may all be unknown or not initially defined. Is an estimate of system size possible?

1.2 A STRATEGY

A large number of unknowns tends to cause procrastination for many capacity planners. From their view, the cost of analysis exceeds the anticipated accuracy of the results. However, one must remember the sizing objectives at this point: sizing estimates will be used by management to consider the feasibility of automation. In other words, a sizing analysis will estimate the "class" of machine (thus, a hardware cost range) necessary for the new automated process. Further, the primary management decision resulting from such a study might simply be to continue or abandon additional analysis plans. The key idea here is to discount neither the quality of analysis nor the importance of the results due to the unknowns. On the contrary, capacity planners must quantify the importance of the decisions resulting from their projections and adjust the depth of their analysis strategies accordingly.

Now that you're convinced a sizing analysis for unknown workloads is worthwhile, let's discuss possible objectives and strategy. Typical objectives might be: (1) estimating workload volumes and resource requirements that the new application will generate when operational; and, (2) estimating the "class" of machine required to process the new workload with an assumed service range.

To address these objectives, FEDSIM developed a sizing strategy that included these four parts: (1) defining the workload; (2) translating the workload to data processing terms; (3) estimating the workload volume; and (4) estimating the resource requirements. A detailed discussion of this strategy is in Section 2 below.

1.3 THE RISKS

Two major risks were inherent in the strategy outlined above. First, data from the manual systems for projecting workload volumes may be nonexistent or of poor quality; these data (if available) may be inapplicable to the automated system due to procedural differences. Second, if the functional design of the automated system is unknown and no implementation plans have been made, it may be impossible to identify suitably equivalent application environments for obtaining resource usage estimates.

These risks are highlighted to indicate the speculative nature of the sizing strategy. However, the identified risks should be weighed against the importance of the resulting decisions before prejudging the validity of the analysis.

2. SIZING METHODOLOGY

This section outlines the approach used for identifying, analyzing, and sizing the data processing requirements for currently manual workloads. This methodology requires four tasks: (1) identifying the major procedures, processes, and/or events that comprise the manual workload; (2) translating the manual activities to data processing work units (e.g., transactions); (3) estimating the volume and distribution of the transactions during normal system operation; and (4) characterizing the transactions by data processing resource requirements (e.g., CPU, I/O, on-line storage). Each of these tasks is described below.

2.1 WORKLOAD DEFINITION

Sizing new workloads is impossible without thoroughly researching the manual processes planned for automation. The objectives of this research should include: (1) understanding the functional work components comprising the manual activities; (2) identifying the existing interfaces among the manual processes and currently automated systems; and (3) establishing the necessary background for understanding the functional requirements of the new automated system. This task consists of two stages: data collection and data minimization.

2.1.1 DATA COLLECTION. A complete review of documentation, standards, and procedures is mandatory. If the new automated system is already under development, a review of the functional design specifications prepared thus far should address much of the background information.

During the background research, attention should be given to reviewing any and all management workload reports describing the manual system. These reports should be gleaned of all quantitative measures such as volumes and trends that may later become the basis for estimating the automated workload volume and resource requirements.

Personnel responsible for the automated system design should be interviewed to discuss any design features that might affect workload volume. Furthermore, the end users should be interviewed to discuss their expectations from the automated system, such as increased productivity and improved management/control. For the capacity planner, this task should result in a functional workload profile of the planned automated system. This profile will identify the most fundamental characteristics of the manual workload (e.g., source, rate) and will define the generic workload requirements resulting from automation (e.g., processing type [batch or interactive], application type [database, process management]).

2.1.2 DATA MINIMIZATION. During the data collection phase, the capacity planner may discover that a large number of variables associated with the manual processes appear to potentially influence the automated system. A significant amount of time can be spent analyzing and debating the value of each variable. Once again, the amount of time available for analysis and the criticality of the result must be weighed against the required accuracy. If the new automated system is still in early stages of design, I suggest that the greater return from the sizing analysis comes not from the absolute quantification of the workload, but rather from identifying which variables have greater impact on workload volumes. What's needed is a tool to assist in quickly eliminating the unrelated variables and reducing what's left to a manageable number. The analysis of variables using linear regression is one approach.

Regression analysis is a technique for discovering empirical relationships between a dependent variable (e.g., workload) and one or more independent variables or factors (e.g., manual processes or sub-processes). Regression analysis finds the equation that best fits the available data and minimizes residual errors due to measurement error or factors not included in the model. Further, using the stepwise regression method systematically adds or removes factors from a regression model depending on whether the factors make a statistically significant contribution to the model's accuracy. Through this mathematical technique, the major manual processes influencing the anticipated automated workload can be identified to minimize the translation process from the manual functions to the automated workload.

2.2 WORKLOAD TRANSLATION

The workload translation from manual functions to data processing transactions involves two steps. First, each of the major activities currently performed manually is related to its automated counterpart. Second, the functional design requirements or known system components are analyzed to determine the definition(s) of automated work units in the automated environment.

2.2.1 MANUAL WORKLOAD MAPPING. Meetings between the capacity planner, system designers, and end users must be held to determine how each major manual workload might be supported and/or performed by the automated system. A synergistic approach can be used to develop workload scenarios from a user perspective for each manual function. Then, using a worksheet approach, a matrix can be produced to define these relationships: (1) what automated activities are required for each manual function; (2) the number and type of automated work units (e.g., screen displays, processes) resulting from the execution of each manual function; and (3) the anticipated user input requirements and output expectations. Comparisons of these scenarios allow the analysts to visualize how the automated system will support its users and to identify repetitious and/or overlapping workloads.

2.2.2 AUTOMATED WORKLOAD DEFINITION. Following the manual workload analysis, the capacity planner probably will rely on his/her data processing experience in comparing the expected user requirements from the new system with other existing automated systems. The objectives of this comparative study should be to determine the initial workload definitions for the new automated system in terms of functional capabilities. For example, this analysis should generally determine the type of automated system required (e.g., batch, interactive), the data sources and data management requirements (e.g., data base architecture), and the categories of anticipated functional work units (e.g., transaction types). These determinations provide the basis for defining the automated system workload in some quantitative measures and distributing the workload into categories according to estimated data processing requirements.

2.3 WORKLOAD VOLUME ESTIMATION

Initial workload volume estimates for the new automated system are possible using the results of the two components of the workload translation process

described above. Management reports and/or documentation on the manual functions must be scrutinized for work volume indicators. The relational matrix produced during the manual workload mapping process provides the vehicle for estimating automated system transaction volume and distribution.

Now is also the appropriate time during the workload analysis to discuss workload growth projections. The manual function documentation may provide some historical perspective to workload growth. However, one must understand that growth projections for the automated system may not be a direct extrapolation from the manual system growth statistics. For example, consider the latent demand issue. Manual system production delays may be occurring due to staffing and/or scheduling constraints. The automated system may improve operational efficiency to the extent that workload queues diminish. Thus, the potential for additional system throughput implies both a higher automated system transaction volume and a variable distribution of transaction types.

2.4 RESOURCE REQUIREMENTS ESTIMATION

Estimating accurate system resource requirements for the automated workload is extremely difficult. Many variables can affect these estimates, including database design, application design, database management discipline, and communications design. Often, a new system design does not dictate a specific hardware and software solution. Therefore, any number of system architectures could be proposed by competitive bid. In such cases, resource estimates are possible only by ad hoc selection of a reasonable system architecture (i.e., database system, user software, etc.) to support an application bearing resemblance to the new automated system. Using this system design and the derived workload definitions, private commercial companies and government agencies operating similar applications can be contacted with specific inquiries regarding the typical resource usage for transactions matching the workload definitions.

3. A CASE STUDY: ANALYSIS AND FINDINGS

This section provides a recent case study conducted by FEDSIM that demonstrates the sizing methodology and clarifies many of the analytical subtleties.

3.1 ENVIRONMENT DESCRIPTION

A major government agency is responsible for the financial management and administration of a huge cash reserve account. This account is under continuous audit to ensure proper cash flow, very similar to the practices incorporated by banks to manage short-term loan reserves. A portion of the account management involves follow-up's on delinquent client payments and client financial background investigations. This portion of the account management workload is a manual, paper intensive process. The agency is currently unable to adequately manage all active receivables to the account due to staffing shortages and the magnitude of the manual workload. Thus, the current operations concentrate only on the high dollar, high risk receivables.

Agency management viewed this practice as unacceptable to their mission responsibilities and elected to automate the manual portion of the account management system. Logically, the issues following this decision included an estimate of the automated system costs, which led to a workload sizing study.

3.2 NEW APPLICATION DEFINITION AND DESIGN

FEDSIM initially reviewed the system design plans and held in-depth discussions with agency personnel to determine a general definition and scope for the new automated system (hereafter, called the "XYZ system"). This information indicated that the XYZ functional requirements had a close resemblance to the large database management systems typically found in data processing today. It was also determined that the manual system workload was distributed among 20 geographically disjoint regions around the United States. The automation plans included analyzing and estimating the host system capacity and the on-line database storage requirements at each of the 20 sites.

FEDSIM also determined from the initial information gathering that the operational environment for the XYZ system would likely be interactive information retrieval, display, and update. The functional requirements of the system would include the management of account receivables, provide a repository for historical case information, assist in the scheduling and priority of investigative work, and highlight accounts impacted by pending Federal legislation.

3.3 SIZING RESULTS

Sizing the XYZ workload for each of the 20 host systems involved four steps: (1) defining the XYZ workload; (2) translating the XYZ definitions to data processing workload; (3) estimating the total transaction volume and the distribution of transaction types for each XYZ location; and (4) estimating the on-line storage requirements (i.e., database size) for each XYZ location. Each step is described below.

3.3.1 WHAT'S THE WORKLOAD. FEDSIM used the agency's description of its account management activities to guide the development of a set of independent variables for estimating the dependent variable, XYZ workload. FEDSIM sought to obtain data representing as many of the major XYZ modules being developed as possible. Data were extracted from the account activity report by geographic region for each of the years 1983 through 1986. Statistical analysis and historical workload comparisons indicated that these data were a reasonable representation of the baseline XYZ workload.

From the documentation and discussions with agency personnel, FEDSIM found that two major activities comprised the XYZ workload: accounts receivable processing and accounts investigation processing. The majority of the available data to theoretically explain the XYZ workload was included in an account activity report prepared for agency management. Three major statistics were found to quantify the accounts receivable work category. These figures were the total active and queue receipts, total active and queue dispositions, and total active and queue inventory. The total active and queue receipts was an appropriate accounts receivable determinant since it represented the volume of potential work arriving on the XYZ system. Components of the accounts receivable portion of the XYZ workload used the following nomenclature in the account activity report: full payments, installment agreements, staff hours, and uncollectible totals. The account activity report also identified quantifiable statistics for the investigations activity. These statistics were staff hours and total dispositions.

As described above, FEDSIM selected as many variables as possible from the account activity report that might influence the XYZ workload. Next, using a stepwise regression technique (i.e., PROC STEPWISE)

from the Statistical Analysis System (SAS), many of these variables were later rejected since they did not significantly affect the dependent variable. A linear regression model using PROC GLM was then developed to determine the workload relationships (i.e., coefficients for the independent variables). Two objectives were met using this model. First, the XYZ workload could be explained through a reduced set of tasks related to the XYZ software modules under development. Second, the estimated model coefficients enabled FEDSIM to derive transactions totals and storage requirements for each XYZ location.

The linear model to explain the XYZ workload eventually took the following form:

WKLD = UC + INS1 + INS2 + PENALTY + INV + OVERHEAD,

where,

WKLD	=	yearly accounts receivables + investigations per geographic region;
UC	=	yearly uncollectible totals per region;
INS1	=	yearly small account installment agreements per region;
INS2	=	yearly large account installment agreements per region;
PENALTY	=	yearly penalty accounts per region;
INV	=	yearly investigations per region;
OVERHEAD	=	Other processing over and above the five major tasks required by XYZ and system overhead required to run XYZ.

The statistics for these variables were all taken from the account activity report.

Further refinements to the SAS model using PROC GLM produced the following linear relationships among the contributing variables:

WKLD = .0058 * UC + 3.66 * INS1 + 5.78 * INS2 + 3.81 * PENALTY + 1.92 * INV + 1846

Model F = 560.32
R-Square = 0.96

The variables INS1, INS2, PENALTY, and INV were all found to be significant at the 99 percent level. The Model F indicates that the entire model as constructed was significant at the 99 percent level. Finally, the R-Square indicates that 96 percent of the variation in the dependent variable was explained by the estimated model. This group of statistics indicates that the XYZ workload was well explained using a minimal number of variables in the model. The independent variables were used to project XYZ transactions, given that workload patterns and the accounts receivable operations procedures do not change.

3.3.2 WHAT'S THE DP WORKLOAD. FEDSIM had already determined that the functional user requirements from the XYZ system resembled a typical database management environment. Further discussions with the user community assisted in the development of a set of functional transaction definitions to characterize the production XYZ workload. The following transaction types were identified: (1) process control; (2) inquiry/display; (3) simple update; (4) complex update; or (5) complex computation. Typical definitions for these transaction types are shown in Table 1.

Table 1. XYZ Transaction Definitions

PROCESS CONTROL:	FUNCTION SELECTION MENU REQUIRES NO ACCESS OF DATABASE
INQUIRY/DISPLAY:	SYSTEM PROMPTS FOR INFO QUALIFIERS SEARCHES DATABASE AND RETRIEVES INFO
SIMPLE UPDATE:	REQUIRES USER INPUT TO SCREEN FIELDS UPDATES DATABASE
SIMPLE COMPUTATION:	REQUIRES USER INPUT DATABASE SEARCH PERFORMS CALCULATION ON DATA RETRIEVED
COMPLEX COMPUTATION:	MORE EXTENSIVE SEARCH MORE COMPLEX CALCULATION REQUIRED

These transaction definitions derived from the workload translation process allowed the XYZ workload to be characterized by transaction type, volume, and estimated system resource requirements. These results are described in the following section.

3.3.3 HOW MUCH WORK. FEDSIM developed a profile of the XYZ workload using the major workload components identified by the workload regression model and the transaction types described above. The linear regression technique identified the significant collection activities related to XYZ and estimated model coefficients of all explanatory variables for the XYZ workload. These coefficients were used with "information screen" estimates for each XYZ function to estimate the total number of transactions for a yearly XYZ workload at each region. These information screen estimates resulted from detailed discussions with users and system designers of the XYZ system. The number of screens and data content for each major XYZ function were identified. FEDSIM assumed that these identified screens for the accounts management activities could also be defined as "XYZ transactions". The basis for this assumption was logical since even the process of scrolling through screen displays at a user terminal requires some interaction with user communications software at the host system, hence an interrupt and some amount of host system processing. Therefore, the mathematical product of the model coefficients and the screen totals provided transaction subtotals for each major accounts management activity. The resultant sum of these transaction subtotals was the estimated total XYZ transaction volume for each XYZ location during a one year period.

FEDSIM also estimated the distribution of transaction types at each XYZ location. From the worksheets previously discussed, FEDSIM calculated the total number of transactions in each transaction type for all major accounts management activities. These figures, when applied as a ratio to the total transaction figures, provided percentiles for each transaction type at each XYZ location. Table 2 shows

the distribution of the XYZ workload by transaction type for each of the major XYZ tasks.

Table 2. XYZ Workload Distribution by Transaction Type

TRANSACTION TYPE	XYZ PROCESS[1] UC	INS1	INS2	INV	PENALTY	TOTAL
Process Control	28.0	28.7	28.7	30.3	40.0	30.4
Inquiry/Display	47.0	32.1	32.1	57.1	51.6	46.9
Simple Update	20.0	29.0	29.0	10.5	8.4	17.6
Simple Computation	2.6	8.0	8.0	2.1	-	4.2
Complex Computation	2.4	2.2	2.2	-	-	0.9
TOTAL	100.0	100.0	100.0	100.0	100.0	100.0

[1] Percent of task by type.

FEDSIM found that process control (30.4%), inquiry/display (46.9%), and simple update (17.6%) would probably be the major transaction types. These figures represent 95 percent of total XYZ processing. The proportions of total transactions represented by each transaction type are also shown in the table.

The XYZ transaction types were then defined in terms of their estimated resource requirements. FEDSIM derived these definitions by conducting a survey of large IBM installations that maintain database management systems (DBMS's) approximating the XYZ system in size and workload. The results of FEDSIM's survey are summarized in Table 3. Note that the resource requirements for each transaction type indicate a best/worst case range. Due to time limitations and to the variety of commercially available DBMS's, FEDSIM reported only an approximate range. Improved accuracy is possible only after XYZ database design and implementation plans are finalized.

Table 3. XYZ Transaction Resource Definitions

TRANSACTION TYPE	RESOURCE REQUIREMENTS CPU TIME (SECONDS)[1] MINIMUM	MAXIMUM	DISK I/O MINIMUM	MAXIMUM
PROCESS CONTROL	.005	.010	2	5
INQUIRY/DISPLAY	.040	.080	5	20
SIMPLE UPDATE	.300	.360	5	20
SIMPLE COMPUTATION	.200	.500	10	30
COMPLEX COMPUTATION	.600	1.130	30	100

[1] CPU estimates based on IBM 3081K.

FEDSIM used these workload distributions and transaction definitions to determine the total XYZ transaction volume and resource requirements for each XYZ location. The 1986 manual workload volumes, transaction distributions, and resource usage definitions were the basis for these estimates. These data are shown in Table 4. In practice, the capacity planner should update the distributions to derive new workload sizing estimates as more complete data become available.

Table 4 shows the estimated 1986 XYZ workload volumes. Transaction totals are estimated for a one-year period. Assuming a normally distributed arrival pattern, a 40-hour processing week, and a 50-week year, FEDSIM also estimated the average hourly workload.

The Los Angeles region was predicted to have the largest estimated workload, with over 41.4 million transactions for the year, or 20,700 transactions per hour. The average XYZ system would process approximately 24 million transactions during a year or 12,000 per hour.

Table 4. XYZ Workload Estimates, 1986 Base

XYZ LOCATION	TOTAL TRANSACTIONS[1]	TRANSACTIONS PER HOUR[2]
Baltimore	11.2	5,600
Boston	20.8	10,400
Philadelphia	11.9	6,000
Buffalo	15.9	8,000
New York	27.4	13,700
Newark	14.0	7,000
Houston	37.6	18,800
Dallas	31.0	15,500
Denver	31.1	15,500
Seattle	31.1	15,600
San Francisco	32.3	16,200
Los Angeles	41.4	20,700

Detroit	22.9	11,500
Chicago	26.4	13,200
St. Louis	11.8	5,900

[1] Millions.
[2] Assumes normally distributed arrival.

3.3.4 What Size System

3.3.4.1 Host Processor Size

To determine the "class" of machine required for processing the XYZ workload, FEDSIM developed an analytic model using BGS System's CRYSTAL and BEST/1 products. Analytical models are structured mathematical relationships used to describe the dynamic behavior of hardware and software components of computer systems. These models can estimate the performance of computer systems and are often used to predict the data processing requirements for newly-designed systems. They are especially useful for comparative analyses since changes to workload descriptions and hardware configurations can be done relatively quickly and easily. The agency was particularly interested in (1) estimating the "class of machine" (i.e., size) necessary to support XYZ at each location and (2) using the flexibility of analytic models to evaluate the effects of environmental changes (i.e., "what if" analyses).

Using the analytic model to relate the resource estimates to the workload volumes, FEDSIM estimated the CPU time and disk I/O requirements. These statistics are shown in Table 5. FEDSIM also estimated ranges of CPU busy and disk I/O rates. The CPU estimates assume an IBM 3081K processor, a 40-hour processing week, and a 50 week year.

The Los Angeles region would have the largest estimated resource requirements. The 41.4 million transaction workload would consume approximately 1,000 to 1,600 CPU hours during a year. An IBM 3081K processor would be utilized 52 to 80 percent during prime shift. The Los Angeles workload would also perform between 189 and 691 million disk I/O's, or between 26 and 96 I/O's per second. The average XYZ system would require 573 to 842 hours of CPU time and 108 to 395 million I/O's per year.

Table 5. XYZ Resource Estimates, 1986 Base

XYZ LOCATION	CPU ANNUAL (HR)[1]	CPU USAGE (%)[2]	DISK I/O ANNUAL (*10^6)	DISK I/O PER SEC[2]
Baltimore	273 - 425	14 - 21	51 - 186	7 - 26
Boston	469 - 733	23 - 37	92 - 340	13 - 47
Philadelphia	274 - 428	14 - 21	53 - 196	7 - 27
Buffalo	378 - 588	19 - 29	72 - 263	10 - 37
New York	549 - 866	27 - 43	118 - 436	16 - 61

[2] Based on 2,000 prime shift hours per year.

3.3.4.2 On-line Storage Requirements

FEDSIM reviewed the XYZ database design documentation provided by the agency. This documentation provided the current database schemata (i.e., logical file organization, file element descriptors, record and field lengths) under development for XYZ. FEDSIM then interviewed agency XYZ project personnel to identify the relationship of the XYZ workload (i.e., accounts receivables + investigations) to the schemata. These relationships effectively became numerical multipliers to determine the relative file sizes within the database. Then, the sum of the relative file sizes became the estimated total on-line storage capacity (in bytes) to accommodate the XYZ database at each location. However, one must recognize that this statistic represents the storage capacity required if the XYZ database is allowed to grow unmanaged and uncontrolled during a complete XYZ production year. The frequency and extent of database management practices, such as reorganizations, archivals, etc., as well as XYZ workload arrival patterns, will have a dramatic effect on the on-line storage requirements at any specified time during an XYZ production year.

FEDSIM estimated the size of the XYZ database in the following manner. The agency's database design documentation identified the types and lengths of records in various files comprising the XYZ database. XYZ project team personnel also provided several other records and corresponding lengths not identified in this documentation that were being considered for the XYZ database.

Agency personnel estimated individual file sizes by projecting the number of occurrences for each type of record based on various criteria. These criteria varied among the record types and were developed based on the experience of the XYZ project team personnel working with FEDSIM on this portion of the effort. These criteria established algorithms for determining the number of records in specific files and for estimating the size of related files in the database structure. FEDSIM developed a spreadsheet using LOTUS 1-2-3 to algorithmically size the total database at each XYZ location. This sizing depended on the actual 1986 manual workload, the estimated workload from the regression model, and the estimated number of accounts at each site. The total XYZ database size was the sum of the lengths of all record types included in the XYZ database or resulting from XYZ processing, multiplied by the number of occurrences per year of each record type (these statistics were estimated by the agency personnel).

The agency was not certain how database archives would be accomplished. However, FEDSIM decided that one of three alternatives would probably be used: (1) data written to an on-line archive file but not removed from the active database; (2) data written to an on-line archive file and removed from the active database; or (3) data written to an off-line (e.g., tape) archive file and removed from the active database. Option 1 would require the most on-line storage and is not practical unless an archive backup is required. The major difference in storage requirements due to the archive file depends on Option 2 or Option 3. With Option 2, the size of the archive file essentially equals the storage required to maintain the data in the active database (i.e., the on-line requirement stays the same with or without an archive file). With Option 3, the on-line storage requirement decreases by the size of the archive file.

The XYZ database size estimates are shown in Table 6. This table shows two size estimates in bytes for each region. One estimate indicates the database size

assuming Option 2 above; the second estimate assumes Option 3. For purposes of discussion, a single IBM 3380 disk can store 2.52 gigabytes of data, or over two and a half billion bytes of data. Therefore, the storage estimates indicate that each XYZ site would require the storage equivalent to one to two 3380-size disks. (Of course, to ensure good performance, a database would be spread over several partially-filled disks on separate channels and controllers.)

Table 6. XYZ Database Storage Estimates, 1986 Base

XYZ LOCATION	DATABASE STORAGE (GB) NO ARCHIVE[1]	OFF-LINE ARCHIVE
Baltimore	1.45	1.28
Boston	1.69	1.47
Philadelphia	2.55	2.25
Buffalo	2.00	1.77
New York	3.55	3.14
Newark	1.91	1.70
Houston	4.57	4.04
Dallas	3.77	3.35
Denver	3.78	3.34
Seattle	3.75	3.29
San Francisco	3.65	3.19
Los Angeles	4.56	4.01
Jacksonville	3.12	2.78
Atlanta	3.10	2.69
Nashville	2.55	2.28
Indianapolis	2.26	2.02

[1] With archive file, if data compression occurs.

4. SUMMARY

This paper provides a structured approach to addressing capacity questions regarding unknown workloads. The usefulness of this technique should be viewed with regard to the risks associated with the results. The sizing methodology presented herein can be summarized by the following four steps:

(1) Define the workload in NBU's;

(2) Translate the NBU's to data processing work units;

(3) Estimate the workload volume;

(4) Estimate the resource requirements.

Perhaps, the most significant benefit from this approach, as echoed by the case study agency, was that the systematic method highlighted the system design factors contributing to the automated workload, identified the previously unquantified workload factors, and provided techniques and direction for further analyses. With this analytic structure in place, the sizing model can undergo continual refinements and validations up to the point of hardware acquisition.

AN EXPERIMENT IN THE CALCULATION OF CAPTURE RATIOS

John F. Temperly
and
Robert J. Hardman
National Advanced Systems

ABSTRACT

Several activities undertaken by Capacity Managers demand a knowledge of local, site, CPU complex, and workload subset specific capture ratios. Many organizations have no way of determining other than system-wide capture ratios.

This paper discusses an experiment conducted to find a means of facilitating the calculation of capture ratios for individual workload groups. These calculations have been based on data readily and commonly available from a standard MXG Performance Data Base.

Comments are made on the validity and effectiveness of some methods of workload group capture ratio calculation and on a means of establishing a prima facie accuracy for the results obtained.

The evaluation pays particular attention to the multiple linear regression method of workload group capture ratio calculation recommended by Dr. Barry Merrill in his book relating to MXG.

1.0 INTRODUCTION

1.1 MEASUREMENT OF UTILIZATION AND PERFORMANCE

In the IBM MVS operating system environment, manuals and other capacity management literature provide considerable discussion of the shortcomings of software tools which measure system utilization and performance.

One common theme is the inability of those software tools to account for the CPU utilization.

Total CPU (busy) time must be calculated by taking the difference between the elapsed time of the measurement interval and the wait time accumulated for the CPU complex during that interval. The full, accurate measurement of time consumed in processing individual subsets of the total workload is rarely accomplished and reported. Typically, the Sum of the times recorded for all subsets is less than Total CPU time calculated.

1.2 THE CAPTURE RATIO CONCEPT

The concept of a Capture Ratio is simple and may be familiar. The ratio of the Sum of workload subset CPU times to the Total CPU time, defines the System-wide Capture Ratio.

The aim of the experiment documented here was to find a satisfactory method of calculating capture ratios for workload subsets. Such methods involve adjusting subset CPU times by distributing the overhead of the system (the difference between Sum and Total CPU times) across the workload subsets. The ratio of the CPU time measured for a subset to the adjusted subset time, defines the Capture Ratio for that subset of the workload.

1.3 CAPTURE RATIO VALUE VARIATION

There is a second theme common in the literature. It is that Capture Ratios for any workload will vary under different measurement circumstances.

Each CPU product which is an implementation of the standard application compatible architecture, uses its own numbers or sizes of CPU architectural components. These include the number of instruction processors, cache buffer and main storage sizes, or uniquely microcoded performance enhancements.

Operating system versions not only make use of or manage the CPU sources differently, but also create and deal with overhead processing in their own way.

Other program product software changes, for example, to compilers, major application subsystems such as CICS, or the introduction of 4GL's or a DBMS to reimplement the processing of the same functional workload, will result in different overhead demands on the operating system.

Most importantly perhaps, the measurement and accounting tools are constantly being enhanced. Their ability to measure CPU consumption generally has improved with each new version. Version changes have often brought with them redefinition of some of the quantities measured or perhaps a shift in the method of measurement.

Any differences in these system features between CPU's used to accomplish processing, or any changes to them during the life of a particular CPU, may impact the capture ratio for a given workload.

2.0 REASONS FOR CALCULATING WORKLOAD GROUP CAPTURE RATIOS

There are at least three reasons why capture ratios for individual subset workloads might be important.

2.1 WORKLOAD FORECASTING

Probably the most common is the need to establish a reasonably accurate base on which to build estimates of CPU consumption for forecast workload levels. Subsets of the workload not only exhibit differences in forecast growth patterns, but also in their characteristic transaction profiles and the CPU power consumed in processing their typical transactions. For existing applications, use of workload subset specific Capture Ratios in adjusting reported CPU utilization will produce more accurate estimates of the basic quantum of CPU consumption computed for each element of the business workload.

2.2 CPU PERFORMANCE COMPARISONS

CPU performance comparisons at the time of evaluating bids from hardware suppliers, or for acceptance testing purposes to satisfy contract conditions, are becoming quite complex. Many of the comparisons involve the calculation of Internal Throughput Rate (ITR) figures. These figures are based on the processing of a specific subset of the total production workload executed by the machines being compared. The ITR calculations require a knowledge of the Capture Ratio(s) relevant to the specific workload subset for each CPU complex. Only by adjusting CPU resource consumption figures for a specific workload using the related Capture Ratio, can valid ITR comparisons be made between CPU complexes.

2.3 CHARGEOUT

The frequency of CPU power upgrades is increasing with the rapidly increasing demand from users for that power. The occurrence of dynamic allocation of work among the individual CPU complexes in a service network may also be increasing. Organizations experiencing relatively frequent shifts of workload from one CPU to another may have difficulty in maintaining consistency in billing for CPU time. It is possible that chargeout systems which use CPU and workload subset specific Capture Ratios to adjust system accounting records for individual jobs' CPU consumption will produce more consistent bills for a given volume and type of work.

3.0 "CLASSICAL" APPROACHES

3.1 LITERATURE SEARCHES

As part of the preparation for and continuing review of the experiment in the calculation of Capture Ratios, searches of available literature were conducted. Potential sources searched included various manuals from IBM in particular, and computer held databases, including NAS' SPIRE system, IBM's INFOSYS, and several databases of abstracts available through the Australian National Library.

In all searches, care was taken to narrow down the volume of "hits" by requesting that only those references which specifically dealt with the calculation of the ratios were returned. Very few references were returned as a result. No attempt has been made to determine whether the search criteria were, in fact, too narrow, or whether there is simply not a lot written on the subject.

A clear pattern emerged in spite of the low yield from the searches. It could be said that two classical approaches to capture ratio calculation for workload subsets exist. The first is what might be termed the heuristic approach, while the second is based firmly on the use of multiple linear regression in the manner proposed by Merrill, mentioned earlier.

3.2 APPORTIONMENT HEURISTICS

Heuristic methods proposed included time-consuming trial and error, starting from a set of published ratios and adjusting them until a good consistent fit is found for the measurement data for the user's own site. No reference described a successful attempt to use this method, nor was any useful level of detail for unsuccessful attempts revealed.

Other common heuristic methods are the variations on the theme of apportionment. This approach calls for the overhead or time not "billed" to any specific workload subset, to be allocated to the subsets in proportion to the consumption of a known measured resource.

IBM's SMF/RMF software provides a breakdown of time accounted for each performance group for an MVS system as SRB and TCB or CPU time components. The usual method of apportionment of overhead time is in terms of the relative amounts of SRB time recorded for the groups. This method is based on an assumption that overhead work performed by the CPU is likely to be related to requests made for operating system services by user tasks. Such a method has an appealing simplicity and readily permits the retention of performance groups as the workload subsets under consideration.

Alternatives for the basis for apportionment come to mind, e.g., the ratio of SIO's attributed to the different workloads.

3.3 MULTIPLE LINEAR REGRESSION

The general form of the multiple linear regression equation is:

$$Y = b_0 + b_1 X_1 + b_2 X_2 + ... + b_n X_n + e$$

In the Capture Ratio calculation:

Y is the total CPU resource consumption during a measurement interval (total active or busy time),

X_i represents CPU resource actually measured for a specific workload (part of the CPU busy time),

b_0 is the intercept,

b_i is the estimate of the true regression coefficient which describes the relationship between total CPU resource usage and that of the individual $workload_i$, and

e is an error term.

In an ideal world, each of the b_i's would have the value 1.0, all of the total resource consumption being accounted for by one workload subset or another. In the real world, this is not the case. Theory associated with the notion and phenomenon of Capture Ratios says that the regression coefficient estimates (b_i) should all be positive, should all be greater than or equal to 1.0, and in fact b_i is the reciprocal of the Capture Ratio for $workload_i$.

4.0 AVAILABLE TOOLS

At the outset, it was recognized that the BGS Systems package, CAPTURE/MVS, has gained acceptance as a tool which provides a source of the information required. However, there is a need for a low- or no-cost alternative which provides an interface to other commonly available capacity management software.

Many Capacity Managers are becoming quite familar with Merrill's Expanded Guide to Computer Performance Evaluation (MXG) and the SAS based package of routines that both SAS Software and Dr. Merrill market as an aid to performance analysis.

MXG is the basis of one of two major components in the NAS Capacity Tool used by NAS System Engineers as a support aid for customers wishing to profile the performance or resource utilization of their computing systems, or to model systems to predict performance. Neither the Tool nor the standard MXG code includes a routine for calculating workload specific Capture Ratios.

5.0 THE DO-IT-YOURSELF MXG EXTENSION

It seemed reasonable, given the requirements, the environment and available tools, to use Dr. Merrill's ideas and the MXG portion of the Tool as a starting point for developing a DIY Capture Ratio calculation routine for subset workloads. Consequently, a SAS program was written to interface with an MXG generated Performance Data Base (PDB) to implement both an apportionment approach and the multiple linear regression method of determining the ratios.

The apportionment was affected by the allocation of overhead time according to the relative amount of SRB time recorded for a performance group. SAS' PROC REG was used as the regression routine.

Data available as input to the SAS program were PDB's built from samples of SMF/RMF data from two NAS customer sites in Australia and from a third site in the USA. Standard MXG code was used in the reduction of the SMF/RMF data to an MXG PDB. As much detail as possible was retained by leaving unchanged the workload subset groupings and using the sites' performance groups as subset definitions.

6.0 INITIAL RESULTS

The initial attempts at calculating workload specific Capture Ratios gave rise to some quite unsatisfactory, if surprising results.

Initial executions of the SAS routine which analyzed data from an NAS Australia customer, produced valid ratios from the apportionment, negative regression coefficients for some workloads (performance groups) and rather large magnitude intercepts (b_0's). The negative coefficients were a particular concern as in the context of the "theory" of calculating the ratios via regression, a negative coefficient or one less than 1.0 has no validity. An intercept term of any size required interpretation.

At this point, it was decided to examine the statistical validity of the method. Statistical and mathematical consultants SIROMATH Pty. Limited were asked for an opinion. Also, discussions took place directly with Dr. Merrill as well as with representatives of International System Services Corp. (ISS), purveyors of ISS-THREE, a Capacity Planning and Modeling Package.

7.0 FEEDBACK FROM DISCUSSIONS WITH EXPERTS

7.1 SIROMATH COMMENTS

SIROMATH went so far as to suggest that the use of multiple linear regression might be invalid for any number of reasons. Their reasons included the possibilities of autocorrelation between workloads and of a time variation in the nature of any relationship between total and specific workload related CPU resource consumptions.

While this may well be true, it was decided at the time not to mount a project with SIROMATH to find the best method, given that they admitted to being unfamilar with the physical world aspects of the problem. A fully rigorous approach to the statistics was seen to be unwarranted as a pragmatic approach is all that is required.

7.2 DR. MERRILL'S COMMENTS

Discussion with Dr. Merrill threw a good deal of light on the subject. It should be noted that from a limited number of observations, attempts were being made to find a regression relationship between total CPU resource consumption and resource consumption for 17 performance groups in an MVS environment. Also, attempts were made to force a regression without an intercept term, an optional feature of SAS' PROC REG, basically because it was believed that the whole idea was to apportion all overhead to individual (application/user) workloads and consequently an intercept had no meaning or place in the equation.

The following are the main comments and suggestions made by Dr. Merrill in an initial discussion:

a. There is no need to remove the intercept term from regression analysis of Performance Groups (PG's) CPU time consumption to determine Capture Ratios.

b. The intercept represents work going on in a system with all (user) PG's "at rest", i.e., the MVS dispatcher, SRM, RMF, etc. are all simply cycling around looking for things to do, or measure, or on which to report.

c. The intercept value should be small and represent a low percentage of the total work and CPU consumption in a busy system, otherwise:

i) a performance group of significance has been missed or;

(ii) in deliberately leaving out PG's not of prime interest from the equation, too much has been attributed to the idling system and probably to the error term as well.

d. Use observations from Peak Hours only, especially in non-XA systems.

e. It is necessary to combine like workloads, e.g., PG's of all JES nodes or all TSO response periods, into a logical PG or workload type group for purposes of the regression.

f. Plot measurements of each PG's resource consumption against time, using SAS, to assist in removal of outliers. They should be easy to pick visually.

g. PG's with bi-modal workloads:

(i) will show up in graphs, and
(ii) will give strange results.

h. Typically, in performing the calculations to derive capture ratios, Dr. Merrill has used 30 days data with 6 observations from the peak periods of each day.

After making many of the changes Dr. Merrill suggested, it was possible to go through with him the amended code and the results it was producing at CMG in Las Vegas. At that time, he made further suggestions, mainly concerning the graphical presentation of the initial data. The changes were to permit IEBIBALL processing to identify potentially troublesome outlier observations. He also recommended the use of SAS to plot the residual values (actual-predicted) of total CPU resource consumption, based on the sets of Capture Ratios calculated by the routine.

7.3 COMMENTS FROM ISS

Discussions with the ISS personnel were brief and aimed at determining whether their package attempted to calculate Capture Ratios and, if so, by what method. ISS-THREE does attempt the calculation by apportioning unassigned overhead to specific workload groups in accordance with the ratio of the reported SRB resource consumption accounted for by the workloads.

8.0 DATA RELATED ISSUES

8.1 NUMBERS OF OBSERVATIONS

It has been suggested that a rule-of-thumb (ROT) for regression analysis of data similar to that processed in the experiment is that there should be between 10 and 20 observations for every independent variable in the equation. The thought behind this ROT is that a certain minimum number of observations is required before regression analysis will provide any worthwhile result, and that the numbers of observations suggested are necessary if analysis is to have any chance of determining properly whether the established regression relationship is statistically significant.

8.2 GROUPING OF OBSERVATIONS

Following Dr. Merrill's suggestions, it was decided that an adequate grouping of observations into more general workload subsets was required. Data from PG's was grouped into five subsets:

-BATCH
-TSO
-CICS
-DBMS
-OTHER

In terms of the ROT stated above, this meant that the data available contained quite sufficient observations for a regression analysis to be carried out satisfactorily and for its statistical significance to be determined. At the same time, it meant that the group to which observations for a particular PG should be allocated was not always clearly defined. This resulted in some arbitrary assignments which may impact results in unpredictable ways and could be a factor in the unsatisfactory results obtained from analysis of the data from the U.S. site (see below).

There is a message here for Capacity Managers they have a role in helping to determine the MVS system's Performance Groups to facilitate their work as well as the dynamic management of system performance or system resource accounting.

8.3 REMOVAL OF OUTLIERS

The SAS routine developed produces six sets of calculated ratios. These sets are obtained by the different methods of calculation of Capture Ratios:

a. Using "unfiltered" data

(i) regression with intercept
(ii) regression without intercept
(iii) apportionment of overhead (ratio of SRB basis)

b. Using filtered data

(i))
(ii)) as above
(iii))

Two approaches to data filtering to remove outliers have been tried. In the first, observations are retained only if the CPU time values are within two standard deviations above the mean. For each observation, measured values are compared with

the mean as a lower threshold and

mean-plus-two-standard-deviations
as the upper threshold

for total CPU time and for each workload group CPU time. The aim here is to preserve a very homogeneous set of observations made at times of relatively peak resource consumption.

The alternative method retains a relatively high proportion of observations where this is important to provision of greater significance to the regression relationship achieved. It does this by preserving those observations with values within one standard deviation either side of the mean (in all instances, total and individual workload groups). Again outliers are removed, improving the homogeneity of the data.

8.4 REPEATABILITY AND CONSISTENCY OF RESULTS

Several references and personnel from the U.S. site mention the need for consistency in results obtained from Capture Ratio calculations. No attempt has yet been made to incorporate any consistency check into the SAS program. On hearing of the experiment, the capacity manager at one site requested a copy of the SAS program to perform some calculation tests himself. Early results based on hourly observation data collected during prime shift were mixed and inconsistent. After twenty days' data (180 observations) became available, however, the results showed a marked improvement in consistency as well as validity. At the time of writing, these tests had continued with up to 40 days data with little variation in the Capture Ratio values calculated after the twentieth day.

9.0 ATTEMPTED VALIDATION AND EVALUATION

9.1 VALIDITY

The SAS program developed has been tested to the point that it works in some circumstances, producing valid ratio values from some PDB data, i.e., positive values between 0.0 and 1.0.

9.2 A CRITERION FOR GOOD RESULTS

The program provides a means for a quick evaluation of which set of calculated Capture Ratios appears to be best - best being defined as the set which results in the smallest range of residual values, depicted graphically.

In testing carried out to date, the best results from the available PDB data have been obtained by regression with intercept, using filtered data.

9.3 ACCURACY - A BENCHMARK

It has been revealed that personnel at the U.S. site from which PDB data was obtained have been calculating workload specific Capture Ratios for their CPU complexes for some years. Their method was not described in detail, but it was claimed that it is based on a trial and error heuristic, calculation being complete when weekly analysis results are stable over a period of about two months for a given complex, operating system version, and microcode level. A curious fact is that the results that they were prepared to share included b_i values, for all the world like estimates of regression coefficients.

These U.S. site results were an obvious benchmark against which to gauge the accuracy of the results obtained from the developed SAS program. The routine has yet to produce results that are close enough to those quoted by the U.S. site to satisfy the author. The results of processing unfiltered data from the site are invalid giving Capture Ratios greater than 1.0. Filtering the data yielded even more unsatisfactory results as the process left a mere six observations on which to base calculations.

It is clear from examination of the program's graphical output that the U.S. site data which provides one observation for every quarter hour prime shift period for a week, is far from homogeneous. Data "conditioning" issues need to be resolved before the experiment can be considered to have been completed.

10.0 CONTINUING THE EXPERIMENT

The experiment has life in it yet if it is to reach the desired conclusion of consistently producing valid and accurate workload subset Capture Ratios from the widest possible range of data processed. The SAS program developed needs more testing to overcome the impact of poor data conditioning on its results and a calibration of the results against those of accepted packages needs to be performed.

It seems obvious that a comparison of the SAS routine's Capture Ratio values with those produced from the same data by either CAPTURE/MVS or ISS-THREE would be of value. This will be undertaken. A site possessing one of those tools has been identified and agreement reached for SMF/RMF data from that site, together with results produced by that package, to be made available for analysis and comparison.

11.0 CONCLUSION

Already the project has produced results which are of value in workload forecasting, to CPU complex performance comparisons, and possibly to chargeout calculations.

The project might also provide insight to others who have seen the need to embark on the exercise of calculating workload subset Capture Ratios for themselves. It will certainly be of value in pointing out some of the issues that need to be addressed in such an undertaking.

12.0 ACKNOWLEDGEMENTS

The author is indebted to many people for their contributions to the progress of the experiment or their forbearance while it proved to be a consuming, if part-time obsession. In particular, acknowledgement must be made of the assistance received from Bob Hardman for acquiring the U.S. test data and his encouragement to continue with the experiment. Dr. Bruce Howarth provided some suggestions for incorporation into the program and a critique of an early draft of this paper. Dr. Barry Merrill contributed several suggestions during our discussions and markedly improved the author's insight into the problem. Bill Gibson was patient with a relative novice. He demonstrated some clever techniques for including conditionally interpreted code into SAS programs, thus overcoming some data processing generalization difficulties. The author's wife was the most forbearing.

THE USE OF REGRESSION ANALYSIS IN THE CALCULATION OF CAPTURE RATIOS

Mel F. Kirshin
C-I-L Inc.

ABSTRACT

One of the most basic technical issues faced by all capacity planners is the calculation of capture ratios; however, most capacity planners will use rules of thumb or resort to hit and miss iterative methods when it comes to this ultimately critical statistic.

Although regarded by many practitioners as a dangerous method, when used correctly it will yield reliable results. This paper presents C-I-L Inc.'s experience with regression analysis (SAS PROC REG) to calculate capture ratios.

1. BACKGROUND

1.1 CAPTURE RATIOS

Anybody who tracks and forecasts load needs capture ratios. This is because you normally track load by workload categories, e.g. TSO, Batch Production, IMS etc. By assigning unique performance group numbers to these workload groups, you may obtain TCB and SRB CPU time from Type 72 RMF records. However, there is a significant amount of overhead CPU which is consumed by the system and not reported in Type 72's. The total CPU time consumed is, however, reflected in Type 70 RMF records. The ratio of Type 72 "captured" CPU time to the total CPU time consumed on behalf of any given workload is called Capture Ratio.

Regression analysis may be used to determine the capture ratios.

1.2 REGRESSION ANALYSIS

Regression analysis is an analytical process by which a line is fitted through a number of points. In the case of a straight line, it is referred to as simple linear regression. If a good fit can be established, then the equation of the line can be used to predict the behavior of the points.

Similarly, in the case of points plotted in 3-dimensional space, a plane may be fitted to the points. This is referred to as multiple linear regression, and is the kind we use in connection with capture ratios.

1.3 REGRESSION ANALYSIS AND CAPTURE RATIOS

How does a plane relate to capture ratios? Consider an environment with two workload categories - Wkld A and Wkld B. Points (SAS(r) observations) for regression can be obtained by breaking the load down into intervals of 15 minutes to 1 hour. Each observation must contain the variables A, B, and C representing the captured CPU time per interval of Workloads A and B and the total CPU time per interval for the system respectively.

We can take several observations and plot them in 3-dimensional space as shown in Figure 1. The values for A, B and C are plotted on the X, Y, and Z-axes respectively. By using multiple linear regression, we can fit a plane through the points. The SAS(R) PROC REG is coded as follows:

```
PROC REG;
   MODEL C = A B ;
```

The output of this procedure is shown in Figure 2. The parameter estimate column (2) gives the intercept term as well as the coefficients for variables A and B. The equation of our plane is therefore:

$$T = 1.21\ A + 1.15\ B + .44$$

The constant term, or intercept, represents the average residual CPU time accruing during the interval. In this case an interval size of 15 minutes was chosen. Our residual is then .44 seconds in 15 minutes - a negligible amount. When the intercept is this small, the capture ratios of A and B are simply the inverse of their respective coefficients in the equation of the plane. The capture ratio for workload A

Figure 2

then is 1/1.21 or .83 and that for workload B is 1/1.15 or .87. Although it cannot be visualized in more than three dimensions, the same concept is valid for any number of workload categories.

Or so goes the theory.

2. THE REAL WORLD

2.1 THE PITFALLS

In reality, things are not so simple. You will find that the intercept will often be close to 10% of the total load. Further, you may find that the parameter estimates (and hence the capture ratios) will be slightly different with each different set of observations used. The solution to the first problem is simple - force the regression through the origin. Although this eliminates the intercept problem, it aggravates the second problem of stability of capture ratios. When faced with such a dilemma, our first instinct is to take the ostrich approach - bury our heads in the sand and use the vendor's rules of thumb.

However, by using the following guidelines, you will produce numbers which are more applicable to your installation than any vendor's general purpose rules of thumb.

3. GUIDELINES

3.1 THE OBJECTIVES

We must bear in mind that capture ratios are only useful insofar as they help us achieve our objectives - Workload tracking and forecasting. Our criteria for accepting a value for any capture ratio must therefore be as follows:

(1) The capture ratios produced by applying regression analysis against a given workload, should reproduce the original total CPU load when applied to the same workload.

(2) The capture ratios determined from one set of observations should match as closely as possible those capture ratios which are produced by another set of observations from the same installation running the same workloads.

It is rather unfortunate that this will never happen. Our aim however, is to get as close as possible to this ideal.

3.2 PREPARING THE DATA

3.2.1 CATEGORIZATION OF WORKLOADS. The keyword here is HOMOGENEITY. All tasks within a workload group should either have similar capture ratios or have a stable mix (ie the proportions of tasks with different capture ratios do not change over time). Otherwise you will find the capture ratios for the offending workload group varying widely from week to week or month to month. Such volatile numbers would be difficult to use for forecasting purposes.

Another precaution is to do a separate regression for each shift, so that you end up with for example prime shift capture ratios and off prime capture ratios. Capture ratios of a particular workload group often change from shift to shift. Each observation therefore should include a SHIFT variable.

3.2.2 DATA MANIPULATION. Some manipulation of SMF data is necessary in order to provide observations in a form usable to PROC REG. In following discussion, I must assume a reasonable level of SAS expertise on the part of the reader.

Type 72's consist of one record per performance group per time interval, However, PROC REG requires that each point (or record) contain a variable for each workload group plus one for total CPU. The transformation which is required can be accomplished in SAS with the aid of PROC SUMMARY as illustrated by the following two workload example using MICS(r) data. For those unfamiliar with MICS, the SCPPGA file contains Type 72 data; PGACPUTM is the captured (TCB + SRB) CPU time; and ZONE is shift.

```
DATA;
   SET DAYS.SCPPGA01;
   DATE=DATEPART(STARTTS);
   IF PERFGRP=1 THEN WKLDA=PGACPUTM;
   ELSE IF PERFGRP=2 THEN WKLDB=PGACPUTM;
PROC SUMMARY NWAY;
   CLASS DATE ZONE HOUR;
   VAR WKLDA WKLDB;
   OUTPUT OUT=CAPTURED SUM=;
```

This code yields a SAS data set (CAPTURED) whose variables WKLDA and WKLDB contain the captured CPU times for the workloads. This SAS data set must be merged (using the MERGE statement) by time interval with Type 70 data (HARCPU file in MICS) in order to attach the total CPU time (CPUnBTM in MICS) consumed during the interval.

If a workload has a particularly small load, ie less than 10% of the average workload, then it should not enter the regression at all. You must include code in your program which will zero out all such workloads. A capture ratio of '1' will then be assigned to these workloads. This will not have a major effect on the outcome of your load tracking since you are dealing with relatively small quantities of CPU time.

3.2.3 SAMPLE SIZE / INTERVAL SIZE. The sample size is extremely important to successful regression analysis. As a rule of thumb, a PROC REG should process a data file whose number of observations is no less than 10 times the product of workload groups and number of shifts. For example, in a case of 12 defined workloads occurring in two shifts, the number of observations being processed by the PROC REG should be no less than 10 x 12 x 2 = 240 observations. If your interval size is 30 minutes, you will require data which covers at least 120 hours of wall clock time.

Interval sizes between 15 minutes and 1 hour have been tested successfully by the author. Any longer or shorter than this range, you are on your own. I suspect, however, that success is relatively independent of interval size.

3.2.4 ENVIRONMENT. All observations should be extracted from the same environment. If a configuration change such as a CPU swap or memory upgrade takes place mid-month, do not attempt to analyze the whole month in a single regression. Rather, do a separate regression for each configuration.

3.3 RUNNING THE REGRESSION

Although more repeatable results are obtained by running with an intercept (see your SAS documentation under PROC REG, NOINT), by specifying NOINT, the increase in accuracy for the period analyzed will more than compensate for the loss in repeatability of the results.

Your actual coding for the PROC REG will then be as follows:

```
PROC REG OUTEST=CR; BY SHIFT;
   MODEL T= WKLD1-WKLDn / NOINT;
```

The OUTEST= specifies a SAS file which contains the Parameter Estimates from the regression. More on this follows:

4. PROC REG OUTPUT

4.1 INTERPRETING THE OUTPUT

Referring again to figure 2, the main statistics to be concerned with are as follows:

The VARIABLE column (1) simply lists the independent variables used in the model. If NOINT is not specified, the variable INTERCEP is also included. As pointed out earlier, the column headed PARAMETER ESTIMATE (2) contains the reciprocals of the actual capture ratios calculated by the model. This is the "Bottom Line" and may be extracted via the OUTEST file. If the INTERCEP variable is present, the residual CPU time for a single interval is reflected here. The R-SQUARE (3) value shown here is the ideal, but rarely achieved in real life. This value reflects the degree to which the model (a plane in the case of two workloads) fits the data. A value close to 1 is good. The column headed PROB > !T! (4) contains values which indicate the significance of each independent variable in predicting the total CPU time, C. A number close to zero indicates high significance.

4.2 VERIFYING THE OUTPUT

Verification of the capture ratios calculated by the model must incorporate the objectives discussed in section 2.2 above.

Print out the totals of each workload group as well as the system total used in the model. Multiply the parameter estimates by the corresponding workload group totals. The result should be close (+-3%) to the system total.

Save the capture ratios calculated each time the model is run against another time period. When capture ratios computed with different sets of data from the same installation are plotted on a vertical scale of 0 to 1, a fairly level line should emerge. The workloads that show a wide change over time are not of a consistent nature and should probably be defined differently. This is particularly important if you are doing forecasting based on current data. If a capture ratio cannot hold still for real data, it certainly cannot be expected to hold still for forecasted data.

It may take some trial and error before you have your workloads defined so that the above two tests are successful. If your major loads are defined OK but some minor loads do not pass the tests, then consider the degree of error that is involved with those workload definitions. You may find that you can tolerate some "bad" results without significantly impacting the accuracy of your load tracking or load forecasting. If you find it impossible to get good results for your major workloads, regardless of how they are defined, then you will certainly have a problem tracking or forecasting with any other method, especially with vendor's rules of thumb. So do not be intimidated by your vendor rep.

CACHING THE TAPE LIBRARY
TAPE REFERENCE PATTERNS AND AUTOMATED TAPE SYSTEMS

Daniel Kaberon
Hewitt Associates

ABSTRACT

Much has been discussed about the widening gap between the power of processor complexes and the basic speeds of the peripherals which feed their appetites. Without belittling the athleticism of the average operator, how has the speed of the operator kept pace with a shop's burgeoning MIPs? What was the average tape mount-time in 1970 versus the present? In many installations, ever-enlarging tape library sizes have caused lengthier walks from a particular tape's residence to its waiting drive. Obviously, solutions to this performance shortfall are not to be made from bringing track and field coaches into our shops to consult with our operators. However the mount-time component of batch execution-time today is larger than the processor component and growing. Knowledge of a shop's fundamental tape reference patterns can be used to exploit the newly announced StorageTek 4400 automated library system as a tape library cache. This paper discusses how to analyze and characterize a shop's tape reference patterns, the issues in caching the tape library, and how to simulate a cached tape library. Results of a study of ten installations will be presented.

TAPE-REFERENCE PATTERNS

Figure 1 shows the normal duty cycle of a tape volume in a library. The tape is created by the act of its first mount. The tape may be remounted thereafter any number of times. I term the interval between creation and last mount a volume's active duty. After its last mount, the volume is reserved in the library until it expires. I term the period from last-mount until expiration, reserve duty. Finally, After the tape expires it is a member of the scratch pool until it is subsequently mounted and the cycle begins anew. By exploring the duty cycles of all the tapes in a library, we learn a great deal about a shop's tape-reference patterns.

This is a study of the use of tape. DASD usage is primarily dataset oriented. Tape is volume oriented. In comparison to DASD, there are no heavily-hit tape datasets.

Throughout this paper I refer to tapes generically. Actually there are two broad tape media categories, IBM 3480-compatible cartridges, which I refer to as Square and basic 3420-compatible tapes in a variety of densities, which I reference as Round. All analyses in this study were performed separately for Round and Square tapes. I felt this general method allowed my approaches to be valid in shops already fully converted to square as well as those with no current cartridge drives but contemplating conversion. In the former case, round tapes and their usage must be fully excluded and in the latter, round-tape usage should be fully predictive of square-tape usage. In all data analyses, the distinction between round and square was directly interpreted from the various raw data sources.

Uccel's Tape Management System's Tape Management Catalog (TMC) is a unique and comprehensive source of information about a shop's tape library. The TMC contains the status of every tape volume in a shop's library. From the TMC we can determine the creation-date and last-reference date of every tape dataset, the scratch status and what will lead to scratching he tape (i.e. expiration date, uncataloging), the tape's density and shape (round of square). We also can learn if the tape is on-site or off-site in some particular vault location. The TMC can accurately provide all the required values for quantifying the active and reserve duty periods of every tape in the library.

By calculating the days between creation and last-reference, we have quantified the active duty cycle (this is known by the SAS variable name days-to-last, DAZ2LST.) We can learn a great deal about tape reference patterns. A cumulative frequency distribution of this variable (Figure 2) shows us how many tapes have a duty-cycle less than or equal to one day, up to two days, three etcetera. From my study of nine sites, the percentage of tapes with duty-cycles less than or equal to one week ranged between 67.3% and 95.0%, mean 84.6. This tells us that the final use of a large majority of tapes is completed within a relatively short period after creation. Tape usage shows a very strong locality of reference. Put another way, if you held every tape that was created in one day, after one week only 15 percent of those tapes would ever be reference again prior to scratching. I also looked at the distribution of the age of tapes from last-use to the date-of-analysis, the current reserve-duty durations. The average site's library's median tape was already 78 days since last reference. Half the tapes in the library had been in reserve duty longer than 78 days. This latter set of statistics refute any idea that the high reference frequency within one week is a function of very short retention periods.

The cumulative frequency of the reserve-duty cycle, will later be used for evaluating various cache sizings.

Our other significant data source is the SMF type-21 error statistics by volume (ESV) record. There is one type-21 record corresponding to every tape dismount and thus corresponding to every mount. The fields which interest us are the VOLSER, date, and UCB-type (round-square shape status). The type-21 is irrelevant to DASD analysis and thus the analyst may have previously overlooked it. There are exactly the same number of type-21 records as the sum of Specific and Non-specific tape mounts in type-30 records for the corresponding intervals.

After sorting the type-21 data by shape and volser, we can count how many times each volume was mounted and recounted for a given period. Using SAS, we can create a Total Mounts variable, TMOUNTS, which carries the total number of mounts for each tape volume. PROC UNIVARIATE with the FREQ option can be subsequently unused to further characterize tape usage. Figure 3 shows the univariate output for one medium-size shop's cartridges for a one-week period.

The MEAN is the mean number of mounts per tape cartridge referenced in this week, (2.06477). The N is the total number of unique cartridge tapes (mounted in a week), 2146. The SUM statistic for this variable is the total number of mounts, 4431. Reading from the frequency distribution, 61.9 percent of the tapes were only mounted once during a week. However, this means

that tapes mounted only once constitute only 1329/4431 = 30% of the mounts. The other 70% of the mounts in this example come from the other 38% of the referenced tapes. The univariate output also indicates that the five most-popular tapes for this week were mounted between 24 and 41 times. Although the data was not as rigorously collected, it appears that no single volser ever made it to a shop's top-five list more than one day in a week's data. Clearly there is no such thing as a heavily accessed tape-volume over time. There is a significant shift to fresher tapes on a daily basis. This differs markedly from DASD where the same several volumes tend to have the heaviest usage every day for extended periods. Obviously we tend to update DASD datasets in place but we tend to write updated tape datasets to different tapes, probably at a higher generation number.

Before we leave the subject of data sources, I want to warn analysts to avoid using type SMF 14/15's (Dataset read and update) for inferring mounts. Although these records are essential for DASD analysis, it is unlikely that mount activity can be accurately determined. Reports based on 14/15's should be viewed with great skepticism. Amongst the 14/15's limitations, tapes may be mounted without a trace in a 14 or 15 if, the datasets is not opened (as in run-time JCL errors) a DD uses more than five volumes. A tape volume which has datasets which are opened and closed several times in a single step will not leave a clear mount history when viewed from the 14/15's. The type-21 record is easier to interpret and more accurate for our purposes.

DOES MOUNT-TIME MATTER?

How much do tape-mount delays matter? The question is complicated since no standard tape-mount time statistic exists in SMF or RMF. To answer the question we must first model how many mount-events a job must await. The mount-event is basically the number of unique operator interactions pertaining to a job. I define

$$M = T - D + 1$$

where:

M is the number of Mount-Events
T is the total number of tapes a job mounts and
D is the number of tape drives the job allocates.

I analayzed a set of 1701 jobs which used tapes, modelling the impact of 60 and 120 second average mount delays. If we assume a 60-second average mount delay per mount-event, then a mean of 32% of execution time is mount delay and 79% of the jobs had more mount-delay than CPU time. If we assume these same jobs were provided 120-second mount delays, then the mean proportion of execution-time due to mount-delay was 49% and 88% had more mount-delay than CPU time. (All CPU timings are based on 3084Q.) As CPU and cached DASD subsystems provide faster service, the proportions of execution time in mount delay will continue to increase rapidly.

We should also be aware that a tape-drive is fully captive to a job from device allocation-time until device deallocation. If one-third to one-half of the devices' allocated time is awaiting mount, reducing mount times substantially can provide a major increase in available tape drives. If we were to reduce the execution time of work by 25% mount-time improvements, this is equivalent to increasing the number of tape-drives by 25%.

What about the cartridge autoloader? Eighty-four percent of the tape jobs in our shop request at least one non-scratch tape. Since a job does not progress until all initial mounts are satisfied, autoloaders alone do not adequately meet the performance shortfall. Note, if any allocation awaits mount the whole job is stalled and the apparent tape-drive capacity increase will not accrue.

Mount time delay is the largest component in tape-based workloads' performance and its importance is growing.

STORAGETEK'S 4400 LIBRARY

The StorageTek 4400 is a blend of standard 3480 tape media and robotics. The literal core of this system is the Library Storage Module (LSM), a dodecahedragonal (twelve-sided) silo holding about fifty-five hundred 3480-compatible cartridges. About the circumference of the silo are StorageTek 3480-compatible tape drives and optionally additional LSMs. The average service-time to fetch and mount a resident cartridge is eleven seconds. The system works in cooperation with its Host Software Component (HSC) which intercepts all tape-mount requests and influences MVS to use a silo-attached or a manual drive depending on whether the 4400 can satisfy the request. Up to sixteen LSM's can be interconnected and tapes can be automatically passed between LSMs to satisfy mount requests. If the robot is incapacitated, the LSM can be opened for flesh and blood human operators to manually retrieve and mount cartridges.

The 4400 elicits one central question, what should it be used for? The 4400 is too expensive to use for storing a shop's entire cartridge library. One cannot devote the 4400 to the heavily-referenced tapes since this paper has already shown there are no heavily used tapes over an extended period.

TAPE LIBRARY CACHING

I propose that we exploit automated tape library systems such as the StorageTek 4400 system as a tape-library cache. By placing an adequate number of scratch tapes and recently-reference tapes within a 4400 and purging tapes unreferenced for some number of days, we can automate a very large portion of tape mounts. We also reserve a number of open cells for adding volumes which were not predicted (cache faults). Reserving vacant cells insures that we do not have to purge a tape as a precondition to adding a tape. Tape library caching will dramatically reduce the turnaround time of workloads which require tape-mounts and improve the consistency of their performance. The purging of unreferenced tapes and the replenishment of scratch tapes only takes place at scheduled Algorithm Service Intervals (ASI), not more than once per day. The basic scheme is illustrated in Figure 5.

To evaluate how well a tape-library cache would work, I built a simulator. The simulator expects that all a shop's scratch mounts are handled from the cache and that the shop removes tapes after some pre-determined number of consecutive days of inactivity, an Unreferenced Interval Count (UIC). The program simultaneously simulates the cache-hit behavior for UICs of 7, 14, and 28 days. (The simulator also allows one to select any three values one wishes to evaluate.) The three test-UIC limit-values are known as LIMIT_A, LIMIT_B, and LIMIT_C. An example of the simulation output constituted Figure 7.

Basically, the simulator uses the TMC to generate the contents of a cache with the prescribed UIC. It then applies the mount history from the type-21 data one day at a time. If a mount is made to a volume created within the selected LIMIT, all that volume's mounts are considered cache hits. If the tape was created earlier than the selected LIMIT-ago then we count the first mount for the volume as a cache miss and the rest as hits. In this case, however, we count all mounts to this volume in the subsequent several days' type-21 data, as cache hits. Total mounts for each day by shape are the tallied into cache hits and misses.

This is a very conservative simulator, due to the limitations of the input data. Because we use the early day's data to partically prime the simulated cache, the meaningful statistics come from the latter days' results.

By using the last full week-day's results, we get a very good indicator of how well the 4400 would function if it could house 7, 14, or 28 days' of tapes. Our earlier cumulative distribution of the reserve-cycle (Figure 6) tells us how many tapes are subsumed to support any particular UIC. By comparing the desired UIC population size to the vendor's offering, hardware sizing is trivial. For the STC LSM, we divide the 7-day reserve-duty cumulative frequency by 5500, the STC LSM capacity size. This yields the number of LSMs which are necessary to keep 7-days' tapes in the cache. Of course the simulator can be re-run specifying a smaller number of days to approximate smaller hardware configurations.

By using the TMC we automatically and accurately factor-out the ongoing conversion of tapes to scratch and elimination of tapes from the library (deletion). We can also remove off-site tapes from our cache population although this was not done in this preliminary research.

In actual operation we would pre-load the 4400 with the appropriate recently-referenced tapes. This would insure that we would achieve at least the simulated hit rates beginning on the first day of operation.

RESULTS

Nine sites participated in a study of tape-reference patterns and caching. Figure 4 summarizes the principle results of this research. I found that using a 7-day UIC, no shop achieved less than a 90% hit rate (mean = 95%). This proportion was achieved by placing a weighted average of only 17% of the shops' cartridge library into Library Storage modules. For example, Site 7 today performs 4,444 mounts in one typical day. The simulator found that using the LRU algorithm, 4,313 could be automated leaving only 131 manual mounts in one day.

If we assume that a STC Library Storage Module can accommodate 5500 tapes, four of the sites could store significantly more than seven days' tapes into a minimal (one-LSM) configuration. In these cases, better hit rates would be achieved than simulated by merely using all the hardware of a single LSM.

In all cases, there were very minimal gains and often very significant costs associated with maintaining 14 or 28-days' of tapes. I cannot recommend paying for additional capacity to reach deeply into this zone of diminishing returns.

Of course the 4400 must be fed and cared for at regular algorithm service intervals. Although the numbers of tapes involved in the ASI processing is large, we have successfully moved the manual aspect of tape processing from an operation which is synchronous to job-processing to one which is dominantly asynchronous to job processing. Furthermore, we can predict the impact on particular workloads whose reference patterns we know, such as those which only reference scratch and recently created tapes. For these workloads, tape mounting has been entirely automated.

CONCLUSION

Tape libraries are accessed with significant locality-of-reference which has not been previously reported. Because each tape mount is a commonly recorded discrete event (through the SMF type-21 record), the preferred method of performance predictions simulation rather than analytic modeling. Simulation allows a considered configuration to be tested without making any significant assumptions yielding highly robust results. All nine sites that were studied achieved better than 90% of their mounts automated by maintaining tapes in the system until they were unreferenced for seven consecutive days. This indicates that tape libraries are ideally suited for caching. Easy and inexpensive to run simulations can accurately identify anomalous environments, where caching maybe ineffective or cost-prohibitive. Using an automated tape library as a cache can make significant tape workloads run as consistently and quickly as current DASD-based workloads.

ANALYZING THE PERFORMANCE CHARACTERISTICS OF 18-TRACK TAPE TECHNOLOGY

William F. Dines, Jr. and Bradley A. Cahill
Storage Technology Corporation

ABSTRACT

With the announcement of 18-track cartridge technology in March of 1984, several new concepts were introduced which have set the direction for future tape products. Although all of the enhancements and characteristics of this new technology seem to indicate a significant performance advantage, in some cases there can be a decrease in tape throughput. A key component of this new architecture is the buffered control unit whose primary function is to mask the slow speed of its attached cartridge transports. This paper will discuss in detail the various features of 18-track buffered control units as well as those issues directly related to 18-track performance. Benchmark results will demonstrate the effect of such features as tape-write-immediate, high speed search and buffer management techniques (i.e. buffer stealing and buffer segment allocation) as well as the effect of blocksize on 18-track performance and capacity.

INTRODUCTION

As advances abound in the information storage and retrieval arena, the inherent performance benefits may not be as self-evident as they appear. One must go beyond the advertised or assumed advantages to assess the actual impact of the technology. A definitive example is the introduction of the 18-track cartridge tape technology. Data buffering and three megabyte per second data transfers are obviously major enhancements to tape performance, or are they? Unfortunately, too much emphasis is given to these benefits and not enough to technology changes such as "back-hitching" and "buffer stealing". Even something as simplistic as the use of small blocksizes has a negative impact on cartridge capacity and effective data rate throughput. The significance of blocksize is, in many cases, overlooked or not addressed because of the application changes required to support larger blocksizes.

It is the intent of this paper to go beyond the intuitive advantages of this relatively new tape technology and review, in detail, the salient characteristics of a new generation in magnetic tape development. The main focus will concentrate on the control unit portion of 18-track tape. The intent is to explore the full potential of all the features and facilities that are currently provided with this technology.

BACKGROUND

The requirement for high speed sequential tape processing is still an important factor in many data processing environments today. The use of 18-track tape has essentially remained the same as with older 3420 9-track tape technology: a growing requirement for online disk dataset and volume backups, for archiving aged and/or low usage disk files, for use as the primary data interchange facility, and for large sequential batch file applications which, for reasons of cost, cannot reside on disk.

The batch window, which utilizes tape resources the heaviest, is still primarily completed between the second and third shifts; that is, between the hours of approximately 7:00 P.M. to 7:00 A.M. As online availability requirements and workloads are expanded into these periods, several problems are encountered. First, the batch window is being compressed, putting a greater demand on the tape subsystem to complete the nightly workload in sufficient time to bring up the online system the following day. Second, any growth associated with online systems typically generates additional workloads to be supported by the batch window. "For a time, there is a classic rush hour effect with jobs waiting on tape resources. Gradually, jobs and networks complete and the backlog of tape demand is worked off". A further review of these tape processing requirements may be found in Friedman M. and Dines W. "Performance Measurement Of Buffered Tape" [1].

18-TRACK HARDWARE

The 18-track cartridge tape hardware can be segmented into three distinct components: media, tape transport, and control unit. A brief review of the media and the tape transport will be provided to illustrate the capacity and performance issues associated with these components. The control unit, which is the key element of the 18-track cartridge subsystem, will be analyzed in greater detail in the following sections.

The media consists of one-half inch Chromium Dioxide tape which is contained in a compact cartridge and is self-threading via a leader block. The dimensions of the cartridge are approximately 4" X 5" X 1". There are no beginning-of-tape (BOT) or end-of-tape (EOT) markers as there is on older 9-track 10.5 inch reel media. The cartridge drive automatically determines the beginning and end of tape.

The current Chromium Dioxide media supports a linear recording density of approximately thirty eight thousand bytes per inch (38Kb/inch). Data is recorded on eighteen

parallel recording tracks with an interblock gap (IBG) size of two millimeters or .08 inches between data records. Each cartridge contains a minimum of 541 feet of Chromium Dioxide tape.

When computing cartridge capacity, two other factors must be considered: data block overhead and unusable tape. There is approximately .009 inches of overhead associated with each data block written to tape and also, approximately 36 feet of tape that is unusable for data recording due to tape leaders, etc.. Because of these factors, 505 feet of usable tape and .089 inches of inter-block gap size are used for all calculations throughout this paper.

The significant features of the tape transport as they relate to the performance issues of 18-track technology are discussed in the remainder of this section. First, a nominal or instantaneous data rate of 3 megabytes per second contributes to performance. As stated previously, data is recorded on 18 parallel tracks with a linear byte recording density of 37,871 bytes per inch. The tape is moved on a reel to reel assembly at 79 inches per second (IPS) for normal read and write operations. For the high speed search facility, tape is moved at the rate of 157 IPS. This feature will be discussed in greater detail in subsequent sections.

Second, the transports are data streaming tape drives and require a significant amount of time to get up to speed, slow down and then backup to reposition the tape at the next record after an interruption. This is called a "back-hitch", and occurs whenever the continuous motion of the tape is interrupted. Because of this action, it is of the utmost importance to maintain a continuous read or write operation for as long as possible.

The third component of the 18-track cartridge technology is the control unit. This buffered, microprocessor driven control unit can connect up to 8 tape transports. Two control units can be configured via a dual control unit communications feature to support a total of 16 tape transports. The initial size of the buffer in a single control unit was 512Kb and has been recently increased to 1 megabyte. Each buffer is divided into 64Kb segments. These buffer segments are allocated to tape drives dynamically and are managed with a least recently used (LRU) algorithm based on tape drive activity. In a two control unit configuration, the subsystem will attempt to balance the workload in order to prevent an overload condition on one control unit. An overloaded control unit can transfer the control of a tape drive to its companion control unit. When this transfer is accomplished, the original buffer space is released and new buffer space is allocated in the other control unit. This is done to optimize the use of the buffer space across both control units and to balance internal path utilization.

The allocation of the buffer segments to a drive can be from zero to four 64Kb segments. For example, a fully configured tape system with 16 tape transports could have 2 segments allocated to each of the 16 drives ((2 * 16) * 64Kb)) = 2048Kb or 2 megabytes of available buffer space. If there is no activity to a tape drive, then the buffer space allocation for that drive would be zero and any active tape drives in the subsystem would be able to use the idle drives buffer segment.

The data buffer is the most critical resource in the 18-track tape subsystem. Data movement between a tape drive and the buffer may be done concurrently with data movement between the channel and the buffer. Data may be written to a buffer segment while that same data is being transferred from the buffer to the tape drive. Once again, the purpose of the buffer is to mask the relativly slow speed of the tape drive from the channel.

There are two distinct types of buffered operations: read and write. Both of these operations are supported differently. A buffered write operation is very straightforward. If the data path is available, data is transferred at channel speed from the channel into the data buffer segment and a "channel end" and "device end" is returned to the host, indicating that the write operation has been completed. The channel is then disconnected from the control unit and may service other operations on the path. It is the responsibility of the control unit on a buffered write operation to ensure data integrity, since the data has not yet been written to the tape drive at this point. Once the data begins to enter the buffer on a write operation, the control unit may begin data transfer from the buffer to the tape drive. If a subsequent data block has been transferred into the buffer for that same tape drive before the previous data block has completed its write operation, then the tape motion can be maintained and the buffer will continue to write the next data block without any interruption in tape movement (i.e. data streaming mode). There are two exceptions to this process: "Tape-Write-Immediate" and "Device Syncronization". These features are reviewed in a subsequent section.

On a buffered read operation, if the data is in the buffer, then it is transferred immediately to the host. If there is no data in the buffer when the host requests it, then the control unit defers the request and disconnects from the channel. The control unit then brings the requested tape drive up to speed and starts transferring data into the buffer. While data is being placed into the buffer, the control unit will attempt to reconnect to the channel in order to begin data transfer to the host. Under microprocessor control, the control unit performs read ahead functions in order to have the requested data in the buffer when needed so data transfer could take place immediately at channel speeds without any elongated start up time or delays.

There is an event that occurs which will cause the subsystem to read the same data blocks from a tape transport into the buffer more than one time. This event is known as buffer stealing and occurs when infrequently referenced buffer segments are reallocated to service more active tape transports. The tape transport that has had it's buffer area stolen is instructed to back up and reposition the media to a specific BLOCKID and wait for the next read request from the control unit.

Buffer stealing usually occurs when more than 50% of a maximum configured subsystem is active and it occurred more often when the buffer size was only 512Kb.

THE BENCHMARK PROGRAM

Throughout this paper, 18-track performance numbers are discussed. Many of the reported numbers were generated by a program written specifically to exercise various 18-track features and produce statistics on that activity. This program is available upon request.

18-TRACK CARTRIDGE CHARACTERISTICS AND CAPACITY

Data blocks and tape marks that are written to 18-track media are each assigned a physical "BLOCKID" number by the control unit. These BLOCKID's are imbedded within the data on the media and are not accessible through normal read operations. Groups of many BLOCKID's are assigned to larger areas on the media called "physical reference values" or "sectors". There are approximately 90 of these sectors on each cartridge. Analogous to DASD, one should think of 18-track technology sectors as DASD cylinders and BLOCKIDs as DASD tracks. BLOCKID's and sectors are referenced throughout this paper.

One of the most important, but often overlooked, characteristics of the 18-track cartridge is the inter-block gap (IBG) size (the space that lies between each data block on the media). The IBG size of current 18-track technology is .08 inches wide. One may look at past tape technologies and assume that this smaller IBG size is just one more advantage, but look again. It is not the size of the IBG that is important, but the amount of tape capacity that is wasted each time an IBG is created. For example, 1600 BPI 9-track technology has an IBG size of .6 inches and a linear recording density of 1600 bits per inch. This calculates to 960 bytes (1600 X .6) of wasted media capacity each time an IBG is created. With the introduction of 6250 BPI 9-track technology, the IBG decreased to .3 inches but the linear recording density increased to 6,250 bits per inch. Although the size of the IBG decreased, the amount of data lost by the creation of an IBG increased 95% to 1,875 bytes. Fortunately, this increase in wasted capacity due to the IBG is offset by the fact that 9-track tape reels remained at 2400 feet and the recording density did indeed increase almost three-fold.

Unfortunately, this is not the case with 18-track cartridges. As mentioned earlier, the IBG size for 18-track cartridges is .08 inches wide and the recording density is 37,871 bytes per inch. It was also mentioned that there is an additional .009 inches of overhead associated with each data block, for a total IBG/overhead size of .089 inches. A quick calculation shows us that there is 3,370 bytes of cartridge capacity wasted each time that a data block is created. Think for a moment about all of the tape files that have a blocksize less than 3,370 bytes. That's right! The gaps are bigger than the data blocks, and more than 50% of a full cartridge is blank tape. These 3,370 bytes become even more important when one realizes that the amount of tape that is available decreased from 2,400 feet on 9-track to 541 feet on 18-track.

The role of blocksize is indeed a key issue. Obviously, the larger the blocksize, the fewer the number of IBG's. The fewer the number of IBG's, the lower the amount of wasted catridge storage capacity. Figures 1 and 2 illustrate this point and compare the capacity of a cartridge when the data is blocked at 2,000 bytes to the capacity of a cartridge when the data is blocked at 32,000 bytes. Notice that the cartridge's capacity increased 143% just by reblocking the data.

BLOCKSIZES AND CARTRIDGE TAPE CAPACITY

TAPE DENSITY --- 37871 BPI (18-TRACK)
BLOCKSIZE --- 2000 BYTES

$$\frac{2000}{37871} = .053 \text{ IN.} + .089 \text{ IN.(GAP\&OVHD)} = .142 \text{ IN.}$$

$$505 \text{ FT.} \times 12 = \frac{6060 \text{ INCHES}}{.142 \text{ INCHES}} = 42{,}676 \text{ REC.(85MB)}$$

REBLOCK FROM 2000 BYTES TO 32000 BYTES

BLOCKSIZE --- 32000 BYTES

$$\frac{32000}{37871} = .845 \text{ IN.} + .089 \text{ IN.(GAP\&OVHD)} = .934 \text{ IN.}$$

$$505 \text{ FT.} \times 12 = \frac{6060 \text{ INCHES}}{.934 \text{ INCHES}} = 6{,}488 \text{ REC.(207MB)}$$

Figure 1.

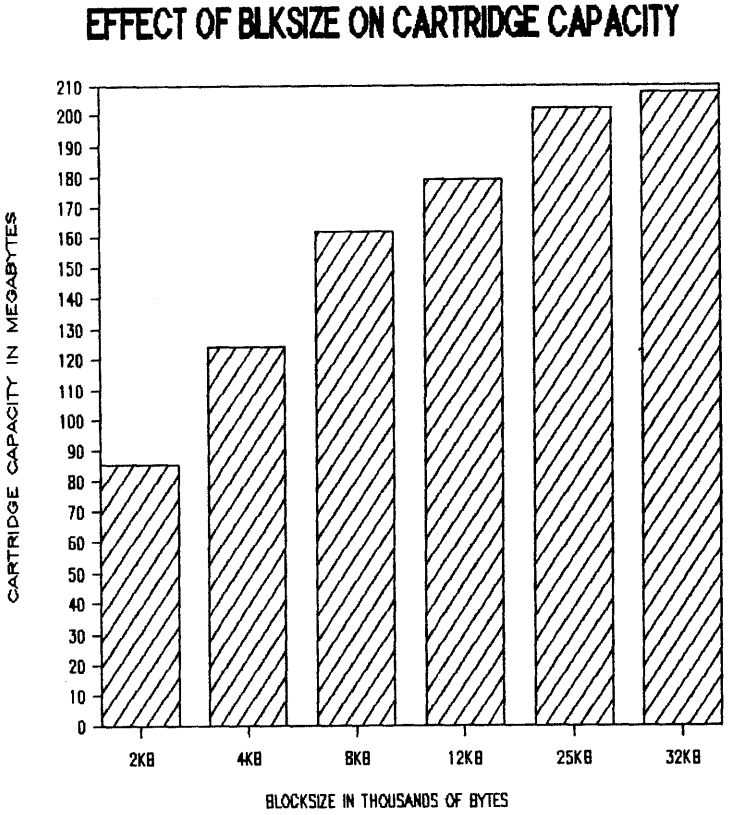

FIGURE 2.

There are other advantages to reblocking files to 32K even if the file is less than a full cartridge. Figure 3 will illustrate this point. If one processes a full cartridge blocked at 2,000 bytes, it takes 42,676 I/O's to access 85.35 MB of data. If that same file is reblocked to 32,000 bytes, only 6,488 I/O's are required to access 207.62 MB of data. That is, you can transfer 2.4 times as much data with 6.6 times less I/O's. Those advantages obviously relate to improvements in performance. Users with extremely small files on 18-track cartridges may consider moving those data sets to high capacity DASD.

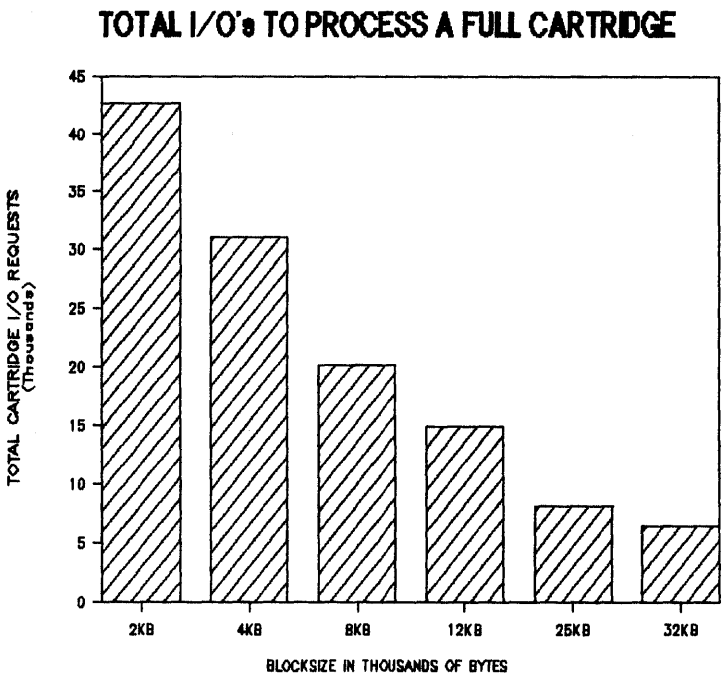

FIGURE 3.

18-TRACK TECHNOLOGY HIGH SPEED SEARCH

High speed search, a new feature with full function mode 18-track tape technology, allows users to randomly access sequential cartridge files. The high speed search feature uses the enhanced BSAM NOTE and POINT macros and/or the enhanced OPEN/CLOSE support to execute two new channel commands. These channel commands process the file BLOCKIDs mentioned in the section entitled 18-TRACK TECHNOLOGY CARTRIDGE CHARACTERISTICS AND CAPACITY. The first channel command associated with high speed search is the NOTE macro "READ BLOCK ID" command. This command transfers two 4 byte data blocks from the 18-track control unit to the host. These two data blocks describe BLOCKID's of records currently being processed or next to be processed by the subsystem. Should a user ever want to perform a high speed search to a particular BLOCKID, it is necessary to "note" the BLOCKID for the desired block and store it somewhere so that it can be retrieved at a later time and used in a "point" function. The second channel command associated with high speed search is the POINT macro "LOCATE BLOCK ID" command. This command transfers one four byte data block from the host to the control unit which describes the BLOCKID of the data block to be located. Information regarding these new channel commands was obtained from the manuals that are referenced in the bibliography.

So what is wrong with high speed search? Users should ask themselves this exact question if they plan to use it for random reads to 18-track files. Prior to high speed search, a user processed a typical tape file by opening it and reading it from start to finish using the QSAM access method. QSAM, as most users know today, is a very efficient access method and will process a sequential file much faster than its predecessor, BSAM. So what's the first thing that has to be done to use high speed search? The application has to be converted from QSAM back to BSAM. This requirement brings up a very interesting question. Is high speed search with BSAM faster than full file reads using QSAM? Well, it depends on how far into the file the high speed search is going and how many records are processed by BSAM once the desired record is found.

In Figure 4, two jobs were executed to demonstrate that, in some cases, high speed search using BSAM can be slower than reading an entire file using QSAM. The first job opened an 18-track file and read the complete file (4,000 BLOCKS) using QSAM. The execution time for this job was 30.669.7 seconds. The second job opened an 18-track file, performed a high speed search to decimal BLOCKID 02000150 (bypassed 146 data blocks) and read the remaining 3,854 data blocks using BSAM. The execution time for the second BSAM job was 37.860.8 seconds. The BSAM job using high speed search ran 23% longer than the QSAM job.

18-TRACK PERFORMANCE STATISTICS

HIGH SPEED SEARCH

QSAM FULL FILE READ VS. BSAM HIGH SPEED SEARCH

HIGH SPEED SEARCH WAS TO BLOCKID 02000150(DEC)

FILE BLOCKSIZE IS 16K BYTES

EXEC TIME	00.30.699.700	00.37.860.800

FIGURE 4.

The degradation in performance that can occur due to high speed search with BSAM can also impact the performance of the entire subsystem. In order to explain the additional contributing factors, we must first look at high speed search or the POINT macro instruction in more detail.

A POINT macro is issued by an application program when the program requires access to a record located some distance in front of or behind the read/write head. The format of the point macro instruction is:

```
[ symbol ]  POINT     dcbaddress
                       ,blkaddr
                     [,TYPE=ABS|REL]
```

dcbaddress

address - ADDRESS OF A DCB IN A-TYPE ADDRESS OR (2-12).

blkaddr

blkaddr - SPECIFY ADDRESS OF PHYSICAL BLOCK ID OR OF THE RELATIVE POSITION NUMBER.

TYPE=

ABS|REL - SPECIFY TYPE OF BLOCKID POINT REQUEST.
- ABS - PHYSICAL BLOCKID IS SUPPLIED IN BLKADDR.
- REL- SUPPORTS TRADITIONAL WAY OF SEARCHING TAPE.

EXAMPLE - SEARCH TO BLOCKID "07001000"

```
GOPOINT   POINT INPUT,BLOCKID,TYPE=ABS
.....     ...   .........
.....     ...   .........
INPUT     DCB   DDNAME=TAPE,DSORG=PS,MACRF=R,
                EODAD=X
.....     ...   .........
BLOCKID   DC    XL4'07001000'
```

In this example, let's assume that the cartridge tape file has been opened and the 18-track read/write head is currently positioned at BLOCKID X'01000004' (sector 01 and block 0004). The application wants to begin reading the file at BLOCKID X'07001000' (sector 07 and block 4096). Under these circumstances, the following are some of the events that would take place.

1. The POINT macro is issued.

2. The 18-track Control Unit receives the "LOCATE BLOCK" command along with the BLOCKID and then disconnects from the channel. The channel is then free to do other work.

3. The 18-track Control Unit then instructs the drive to begin forward motion at a speed of 157 inches per second and to reconnect when the drive reaches the area that is 2 sectors (sector 05) before sector 07. The tape transport then disconnects from the control unit and begins its high speed search. While the drive is disconnected from the control unit, the control unit is able to service another transport. When the high speed search transport reaches sector 05 (2 sectors before the target), it reconnects to the 18-track control unit and slows down to a search speed of 79 inches per second. At this time the control unit is dedicated to servicing the high speed search transport only.

4. The 18-track control unit and transport then perform a "slow speed search" until the BLOCKID X'07001000' is found. When the BLOCKID is found, the 18-track control unit signals end of operation and the next channel command is issued.

The most interesting portion of this high speed search is the fact that once "slow speed search" begins, the 18-track control unit is dedicated to servicing one transport until the desired BLOCKID is found. This type of "control unit lockout" can take as long as several seconds to complete, and this delay degrades the performance of the other transports in the subsystem.

In order to demonstrate the amount of delay time that exists when crossing physical reference areas, it is necessary to execute a job that performs a high speed search to the first BLOCKID in a sector of file and then performs a high speed search to the last BLOCKID in that same sector. The difference between the two time values is the time that it takes to cross the full sector. The results of these test are reported in Figure 5.

18-TRACK PERFORMANCE STATISTICS

ALL TIME VALUES ARE IN FORMAT -- MM.SS.MLS.MCS

BLOCKID NUMBERS ARE IN DECIMAL

	HIGH SPEED SEARCH TO '08001668'	HIGH SPEED SEARCH TO '08001936'
I/O COUNT	1	1
BLOCKSIZE	16,000	16,000
EXEC TIME	00.08.614.800	00.10.435.000

APPROX TIME TO CROSS SECTOR 08 IS 1.8 SECONDS

Figure 5.

The results of this test can be calculated. For example, the first and last BLOCKID's are known, so the number of total BLOCKID's in SECTOR 08 is easily calculated (See Figure 6). The number of BLOCKID's in SECTOR 08 is 269.

```
    TAPE DENSITY    --- 37871 BPI ( 18-TRACK )
    BLOCKSIZE       --- 16000 BYTES

16000
------ = .422 IN. + .089 IN.(GAP&OVHD)=.511 IN.
37871

       PHYSICAL REFERENCE AREA VALUE 008

    FIRST BLOCKID = 08001668 (decimal number)
    LAST  BLOCKID = 08001936 (decimal number)
     TOTAL BLOCKS =      269 (decimal number)

   269 BLOCKS X .511 INCHES = 137.46 INCHES
   (*   LENGTH OF PHYSICAL REF AREA 08   *)

    137.46 INCHES
  ----------------  = 1.74 SECONDS
       79 IPS
```

Figure 6.

If the blocksize is 16,000 bytes, then each block uses approximately .422 inches of tape. If the IBG/overhead length of .089 inches is added to the block length, then it is known that each block actually uses about .511 inches of tape. Multiply .511 inches times 269 blocks and the result is 137.46 inches. Divide the length of the sector by the speed of the transport (79 IPS), and the quotient is the amount of time that it takes to cross the sector. That calculated time value is 1.74 seconds, which is very close to what is reported by the benchmark program.

Remember, the benchmark program only reports the amount of time to cross one sector. It was stated that the slow speed search begins at 2 sectors before the target, which means that if each sector is approximately the same length, then the control unit lock-out on the drive port adapter would be around 5 seconds to locate BLOCKID 08001936. A high volume of this type of activity can severely degrade 18-track performance.

If high speed search is being used, and the blocksize of the blocks being searched is small, single microprocessor 18-track control units may be too busy to service the channel adapters requests, thus locking out data transfers to the host. Dual microprocessor 18-track control units do not have this problem because one microprocessor is dedicated to servicing the channel adapter and one is dedicated to servicing the drive port adapter.

TAPE WRITE IMMEDIATE

Tape-write-immediate (TWI) or write-validity-check is a special mode of operation for write events to 18-track transports. This mode of operation can be requested by coding OPTCD=W in the DCB parameter. It differs from normal write buffered mode in that the 18-track control unit does not signal device end to the host until the data block has been physically placed on the media and verified. This special mode of operation is necessary to service those applications that require a data block to be permanently stored on the media before continuing with any subsequent processing. Because of this type of I/O requirement, tape-write-immediate generally applies to BSAM, EXCP or QSAM (QSAM with BUFNO=1 specified only) applications and applications that code RECFM=F in their DCB and/or do their own data block management.

In normal buffered write operations, data is sent from the host to the control unit. The control unit then places the data into a buffer segment and responds channel end and device end to the host, which allows the requesting application to be dispatched. At some time the transport is brought up to speed, and the data is then physically placed on the media. This I/O overlapping type of operation is what makes the 18-track transport appear to be very fast when indeed it is slower than any of the more recent 9-track tape products.

When a user requests tape-write-immediate, the above mentioned I/O overlapping activity is not allowed to occur. Instead, the data is sent from the host to the control unit. The control unit, while placing the data into a buffer segment, requests that the transport be brought up to speed and then the data is moved from the buffer to the media. When the last byte has been written to the media and verified, the control unit signals end of operation to the host. The host waits for the transport to come to a stop and then backs up to position the media for the next start up operation before it can initiate the next I/O request. This repositioning action of the transport is called a back-hitch, and it can contribute 90 milliseconds of access delay time to each I/O. To put this into perspective, most 9-track tape transports have an access delay time of only 1.5 milliseconds.

So should tape-write-immediate be used? Tape-write-immediate can be used if the application's I/O requirement to 18-track tape does not exceed 10 I/O's per second. In other words, if the application has 90-100 milliseconds of processing time between each tape I/O then this time will allow the 18-track transport to reposition itself, thus masking its motion delay.

If a particular application has to use tape-write-immediate, then there are certain tuning efforts that can be invoked to reduce the impact of this feature. For example, let's assume that a user has previously used 9-track tape for an application and is forced to use 18-track tape with tape-write-immediate. The first option is to reblock the file (if possible) to a greater blocksize. This type of action has three advantages. First, by bringing in more data per I/O, the user decreases the number of I/O operations and thus reduces the number of back-hitch operations and their associated delays. Second, the reduction in I/O operations means a savings in the time involved in MVS IOS overhead. And third, the increase in the amount of data brought in with each I/O would increase the amount of time required to process the entire block. This increase in processing time may help to mask the delay time due to back-hitching.

To illustrate the effect that blocksize has on tape-write-immediate, two batch jobs were executed. One of the batch jobs performed normal buffered write operations at various blocksizes and the other performed tape-write-immediate write operations at various blocksizes. Figure 7 reports the results of the test. Notice that the BSAM job using normal buffered write operations starts off using 2,000 byte blocks with 10 milliseconds of processing delay time for each block. The execution time for this job is approximately 7 minutes and 31 seconds. The BSAM job using tape-write-immediate write operations also starts off using 2,000 byte blocks with 10 milliseconds of processing delay time for each block but runs approximately 53 minutes and 58 seconds. The tape-write-immediate job ran 7 times longer. The 10 milliseconds of processing delay time is not enough to mask the 90 millisecond back-hitch delay time of the 18-track transport.

It is assumed that if it takes 10 milliseconds to process the 2,000 byte block, then it takes 160 milliseconds to process the 32,000 byte block. By reblocking the data, three things

happen. First, both jobs perform 30,000 fewer I/Os, which means 30,000 fewer trips through IOS. Second, there are 30,000 fewer back-hitching events. And third, the increase in processing time for each block gives the 18-track transport enough time to back-hitch; thus, the tape-write-immediate job has a means of masking some of the motion delay of the transport.

So what happens to performance? By using 32,000 byte blocks, the execution time for the normal BSAM job is reduced to approximately 5 minutes and 48 seconds. The big improvement, however, is in the job that used tape-write-immediate. The execution time for this job is reduced to approximately 7 minutes and 13 seconds (See Figure 7) bringing it closer to the execution time of the job that did not use TWI.

BSAM TAPE WRITE IMMEDIATE

Figure 7.

SYNCDEV MACRO

There are other methods besides tape-write-immediate that can be used to ensure that data is stored on the media before another event occurs. There is a new macro called "SYNCDEV". This macro controls data synchronization for 18-track devices that support full function buffered write and relates to write operations only. The SYNCDEV macro instructs the 18-track control unit to write any buffered data in the control unit to the addressed transport before another event can occur for that transport. The SYNCDEV macro is only 100% effective at the logical record level when RECFM=F is specified in the DCB, and either BSAM or EXCP is used or QSAM is used with DCB option BUFNO=1 in effect. Information regarding the SYNCDEV macro was obtained from the manuals referenced in the bibliography.

SUMMARY AND FUTURE CONSIDERATIONS

When used properly, 18-track technology is indeed a high capacity, high performance device. Even first generation 18-track products have inherent advantages over older unbuffered tape technologies because they fully utilize current channel speeds. As demonstrated, something as simple as blocksize plays an important role in both performance and capacity. Establishing large blocksizes as the standard should be a goal for all users of 18-track technology. Making cost effective use of each cartridge should also be a goal. Users may consider stacking smaller tape data sets on one cartridge or moving them to high capacity DASD.

It is also important for users to fully understand the performance implications associated with such features as tape-write-immediate and high speed search. As this paper has demonstrated, tape-write-immediate can severely degrade the performance of an application and the term "high speed search" can, in some cases, be deceiving. Although available as a feature, high speed search most likely is not intended to be used by applications to do random reads to sequential files. It is, however, very valuable for certain functions such as storage management products and error recovery.

As for the future, users can expect nothing but enhancements. Larger buffer sizes and more sophisticated buffer management algorithms are already available and have superceded the initial 18-track offering. One can expect increased linear recording densities, as well as a doubling or tripling of the current number of recording tracks available on current technology. These enhancements necessitate the requirement of faster channels (i.e. 4.5 or 6.0 megabytes per second) and would also provide users with increased cartridge capacity.

And finally, users can look foward to increased automation of 18-track technology. The inherent characteristics of the cartrige size and the way that tape can now be handled has invited the use of automation.

STATIC VS DYNAMIC MANAGEMENT OF CONSISTENTLY VERY ACTIVE DATA SETS

Martha R. Henley and Ingrid Liu
International Business Machines Corporation
San Jose, CA

ABSTRACT

This paper describes the results of analyzing data from 12 MVS complexes. The data sets that were consistently very active during prime shift were identified. These data sets were analyzed to determine how much memory would be required if they were statically placed in an electronic store. In addition the fraction of total non-paging I/O on the system due to these specially managed data sets was determined. These data sets were also analyzed for locality of reference; a hit ratio was determined as a function of the size of the electronic store that was being dynamically managed. All of the consistently very active data sets had good enough locality of reference that a dramatic advantage was seen in managing this data dynamically rather than statically.

The analysis was applied to the problem of evaluating the effectiveness of a cache control unit vs a solid state device. Practical assumptions were made about memory sizes of the solid state device and their prices. Similarly assumptions were made about prices for the cache control unit and what volumes would be attached. For an equal cost cache and solid state device, the cache control unit handled about 1.7 times more I/O than was handled by the solid state device.

The results shown in this document are based on data collected from twelve installations. Individual installations may differ from those considered in this study.

Introduction

Purpose

Typically, a small number of very active data sets represents a large portion of the I/O activity of MVS systems. It is important to understand the characteristics of these very active data sets; overall I/O subsystem performance can be improved through proper management of these data sets. The purpose of this study was to:

1. Identify the consistently very active data sets in several customer installations.
2. Identify the characteristics of these data sets.
3. Evaluate the benefits of two different methods of managing these data sets in an electronic store.
   a. Static Management, or simply loading data into the store and leaving it there.
   b. Dynamic management, or bringing the data into the store as it is referenced and bumping it out of the store on a least recently used basis.

General Approach

In the summer of 1985 seven customers were asked to collect data from a total of 12 data processing complexes. RMF data, dumps of all VTOCs, and GTF SIO traces for all devices were collected. The trace data was taken for two 15-minute periods, one a morning period, and one an afternoon period. The trace times were chosen by the customer to represent typical heavy load times. The traces were timed so that they coincided with the RMF intervals, and were taken simultaneously for all systems in a JES complex. General information about the installation such as configuration and overall workload was obtained from the RMF data. The very active data sets of each customer were identified using VTOC dumps and GTF SIO traces.

Static management of the consistently very active data sets was evaluated by determining what fraction of the non-paging I/O on the system would be to the data sets in the electronic store. The dynamic management was evaluated using Cache Analysis Aid (CAA). The dynamic management algorithms assumed in this simulation program matched those used in the 3880 Model 23 control unit. In other words, the data was moved into the cache when it was referenced starting at the point of reference and continuing to the end of track; the data was removed from the cache on a least recently used basis. Note that although the simulation program used was oriented toward a cached control unit, the hit ratio predictions can be generalized to a main memory buffer managed on a least recently used basis.

The remainder of this report is divided into four sections plus a conclusion. The four sections address:

1. A summary of the workload characteristics of the installations that were studied.
2. The characteristics of the consistently very active data sets in each installation and their classification into four categories.
3. The behavior of the four categories of consistently very active data sets and the amount of I/O captured depending on the category, the size of the electronic store, and the management choice.
4. An analysis of the results a customer might obtain from a cache control unit and a solid state device.

Customer Workload Characteristics

In order to put the detailed results of the study into perspective, it is useful to have some idea of the size of the installation, the type of equipment installed, and the nature of the applications running on the system. This section shows the results of processing the RMF data for the particular interval in the morning for which SIO trace data was available. Thus, it reflects the workload level and mix during the time that data set activity level could be identified. Figure 1 shows the processor models, processor utilization, number of DASD volumes by model, the DASD I/O rates, GB/MIPS, and KIPIO for each of the complexes studied. The gigabytes (GB) on-line were calculated from the device capacities of the on-line DASD volumes. The millions of instructions per second (MIPS) were ballpark estimates based on the CPU model. The thousands of instructions per DASD I/O (KIPIO) was calculated using the MIPS, CPU busy, and the DASD I/O rate. The customers are identified by the first digit of the complex number, and the installation within customer is given in the second digit. There were seven customers with a total of twelve complexes studied. The workload characteristics are summarized as follows:

Characteristics by complex

Cmplx ID	CPU Model	CPU Util	DASD Type	DASD Vols	DASD IO/Sec	GB/ MIPS	KIPIO
11	3081K 3033	98.6% 96.9%	3380 3350 3330 2305	128 22 26 3	305.2 49.3 70.2 19.3	4.8	39.6

Figure 1. Customer Characteristics

Almost all of the customers studied were using MVS/XA. Two had complexes where there was a mix of MVS/SP and MVS/XA systems. About half the complexes were running with JES3 and about half with JES2. The total MIPS estimated for each of the complexes ranged from about 19 to about 56. These are considered to be medium-to-large installations. Most of the complexes were predominantly 3380, although two customers still had a significant portion of their DASD capacity in 3350 devices. Only one customer had installed 3380-E boxes. This is not surprising since the data was collected soon after the announcement of the larger capacity devices.

Fraction of CPU Utilization and EXCPs by Workload Type

The RMF workload activity records were processed to determine the fraction of the load on the system due to various application systems. The Installation Performance Specification from each customer was used to deduce what performance groups and/or domains were associated with which type of workload. The fraction of the total CPU service units consumed by each type of work was calculated and represents the percent of utilized CPU time consumed by each. Likewise, the fraction of total I/O service units represents the fraction of all I/O on the system imposed by each workload type.

Figure 2 shows the fraction of CPU utilization for each workload type. All customers had some batch work during the prime shift. Customers 11, 41, and 51 had a significant amount of TSO load. Complexes 61, 62, and 63 were predominantly CICS on-line production, and the rest were primarily IMS.

Figure 3 shows the fraction of EXCPs issued by each type of workload. The batch component of the workload tends to be more I/O intensive than the on-line applications. This is seen in the larger fraction of I/O consumed by batch than the CPU component.

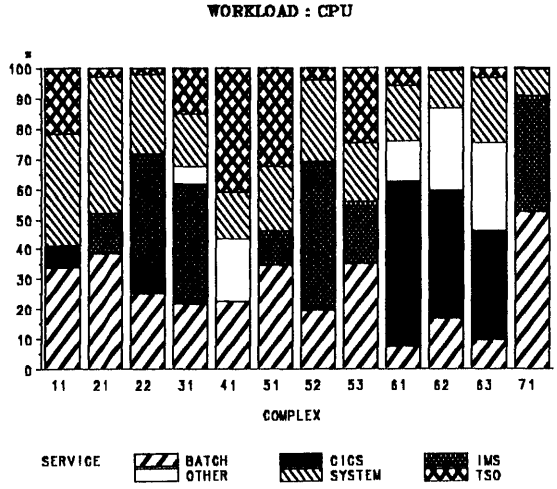

Figure 2. Percent of CPU Utilization by Workload Type

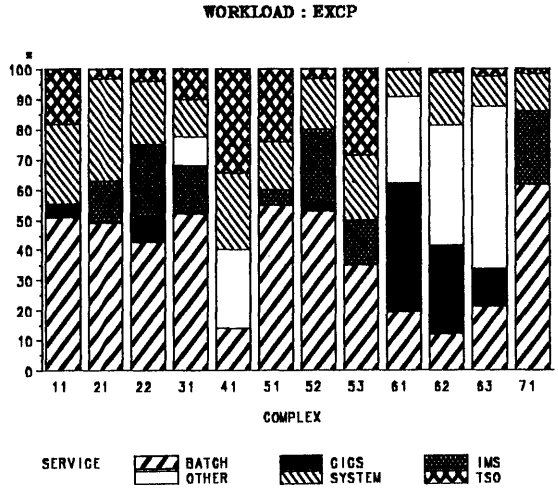

Figure 3. Percent of EXCPs by Workload Type

Consistently Very Active Data Sets

Method of Identification

The morning and afternoon GTF SIO trace data were processed with the VTOC dumps to associate each I/O with a particular data set. The data was processed to produce a list of all data sets that were active during each of the two 15-minute peak intervals. The data sets in the list were ranked by I/O rate. Each customer was asked to describe the use of their ten percent most active data sets. Additionally each customer identified a subset of these top ten percent that were always active during the prime shift, and whether any of these data sets were read-only as opposed to receiving update or write activity. Those data sets in the ten percent most active that the customer noted as being consistently active during prime shift became the consistently very active data sets for this study.

The results of the morning traces were compared to the afternoon traces to ensure that all data sets claimed to be consistently very active were indeed active during both trace periods. The fractions of total I/Os going to the consistently very active data sets in the morning and afternoon were compared and found to be essentially equal. For simplicity in processing, the morning traces were used for subsequent analysis.

The consistently very active data sets were identified and classified into the following four categories:

1. Key System: system control data sets, such as RACF access control, HSM control data sets, JES2 checkpoint, TSO UADS and BROADCAST data sets, Catalogs, SMF data, logs, etc.

2. Spool data sets: both the JES2 and JES3 spool files.

3. Libraries: including IMS program libraries, IMS format and ACB libraries, subroutine libraries, special product libraries, user application load libraries, TSO command libraries, procedure libraries (PROCLIB), and so on.

4. User data: application data sets, such as on-line data bases and indices or application files.

Once identified, there were several kinds of information that could be extracted from the data available for these data sets. The information was available at the data set level and could also be summarized for each of the four categories.

Results by Category

The first item of interest was what fraction of the total non-paging I/O, and what fraction of the non-paging space were due to each of the four categories of consistently very active data sets. Any reference in this paper to percent of I/O is a reference to the percent of non-paging I/O. The percent of I/O and percent of space allocated for each of the four categories of data is shown in Figure 4. The set of bars on the left shows the breakdown for I/O activity and the set of bars on the right shows the breakdown for space. Each bar within the set represents one customer. The height of the bar shows the fraction of total non-paging I/O (or space) attributed to the consistently very active data sets. Within each bar is a further breakdown by data set category. The three installations with the least amount of consistently very active user data were TSO oriented. The fraction of total non-paging I/O that was imposed by the consistently very active data sets ranged from around 25 percent to almost 70 percent! On the other hand the space occupied by these data sets was only 3 to 20 percent of the total non-paging DASD capacity. Of the four categories, the program libraries and key system data sets generally used the least space and had the highest I/O rates.

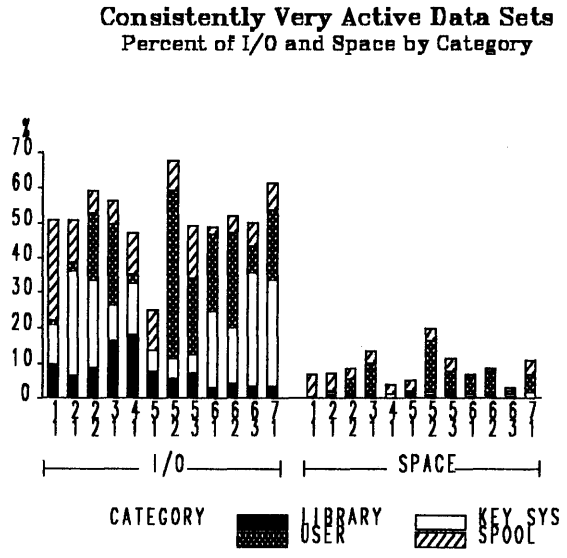

Figure 4. Percent of I/O and Space by Category for All Complexes

The I/O rate and megabytes allocated are shown in Figure 5 along with the percent of non-paging space and percent of non-paging I/O for each category of consistently very active data for each customer. The actual number of megabytes allocated to all the consistently very active data sets varied among customers. The range was from 4,463 MB to 18,649 MB. The total I/O rate to all of these data sets ranged from 104 to 468 I/Os per second.

Figure 5. Summary of Consistently Very Active Data by Complex

Static vs Dynamic Management

Method of Analysis

The consistently very active data sets were identified in the previous section and their size, I/O rates, and usage were described. In this section the focus will be on how dynamic management of these data sets compares with static management. For simplicity the analysis assumes that the electronic store is always non-volatile. In other words, no distinction needs to be made between reads and writes. This mythical non-volatile electronic store that can be managed either statically or dynamically is created for the purpose of the analysis presented in this section. It allows a focus on the locality of

reference of consistently very active data sets. Dynamic management and static management were compared for all data sets by category.[1]

Static management of the consistently very active data was evaluated by assuming that these data sets were being placed in a static store in the best possible order. The highest access density data sets would go in first. The access density is the I/Os per second per megabyte of space allocated to the data set. The amount of I/O handled out of the static store was simply the amount of I/O that went to the data sets residing in a given-sized store.

The ranking of the data sets by access density was based on the morning SIO trace. The I/O handled by the static store was calculated by adding the I/O rates for all of the data sets that fit in a given memory size. These I/O rates are also based on the morning SIO trace. Although the consistently very active data sets have relatively stable I/O rates, there is some variation from one time of day to another. For this analysis the data sets were chosen for the store in an optimal order for the morning I/O trace; variation in the I/O rates would change the amount of I/O handled for any given memory size from what is shown here. [2]

Dynamic management of the consistently very active data sets was evaluated by assuming that they were the only data under a single dynamically managed electronic store with a varying amount of memory. The hit ratios were determined as a function of the size using the Cache Analysis Aid (CAA) simulation program. A special version of the program was used that accepts GTF SIO trace data rather than the more complete CCW traces.[3] This version treats all I/Os the same (rather than distinguishing between reads and writes) and predicts an overall hit ratio. This overall hit ratio is the hit ratio one would expect from a non-volatile store. [4] The management algorithm simulated was similar to the 3880 Model 23 in that it would stage the record accessed and the remainder of the track into the memory, and remove tracks from memory on a least recently used basis. Input to the simulation was created by first merging together the GTF SIO trace data from multiple systems sharing DASD (i.e., from a whole complex), and then selecting only those SIO records for activity going to the consistently very active data sets. The resulting trace records were further divided into four trace files, each containing only I/O for one of the categories. The CAA program was then run to determine the hit ratios as a function of memory size for each of the four categories as well as all of the consistently very active data sets together.

The percent of non-paging I/Os captured in memory was used to compare the performance of static versus dynamic management. The comparisons were made based on equal amounts of memory. For static store the total percent of I/Os captured is the accumulated percentage of I/Os captured by all data sets that fit in a given memory size. For dynamic management, the percent of I/Os captured is the hit ratio multiplied by the total I/O rate of all the consistently very active data sets.

Results

A set of five graphs was produced for each of the twelve complexes studied. Included were 1) the hit ratio for the four categories of data as a function of the amount of memory, and 2) the percent of total non-paging I/O handled out of varying sized stores when managed statically and when managed dynamically; this graph was generated for libraries, key system data, user data, and spool.

Unfortunately, 60 graphs is a bit overwhelming. Since the pattern in the results was strikingly similar in all customer installations, only one example is shown here. Complex 53 was chosen for display. Figure 4 shows complex 53 as having more user and spool data accesses than key system and library data. This is not unusual for production on-line systems, in this case IMS.

Figure 6 shows the hit ratios of each of the four categories of consistently very active data and the hit ratios of all this data managed together for complex 53. The overall hit ratio is shown on the vertical axis, and the MB of cache memory is shown on the horizontal axis.

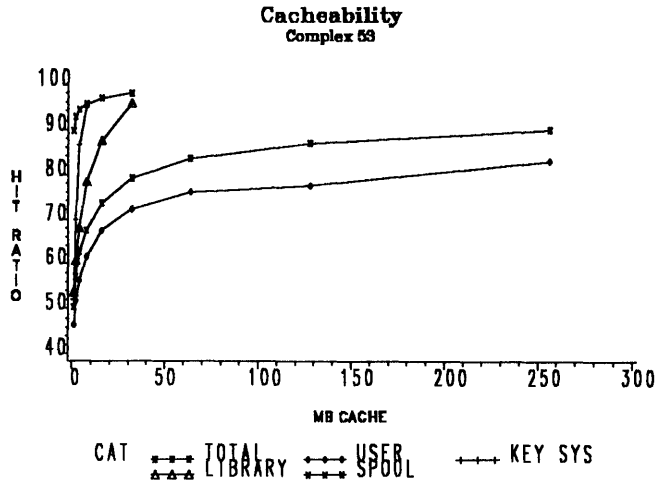

Figure 6. Hit Ratios by Category for Complex 53

The best locality of reference, as indicated by very high hit ratios for small amounts of cache memory, is seen in the spool data. Key system control data and libraries also have very good locality of reference. User data tends to have a more random reference pattern resulting in lower overall hit ratios for a given amount of cache than the other categories. The overall hit ratios for complex 53 are heavily influenced by the locality of reference in the user data; recall that this IMS production system had fewer key system and library accesses than a TSO installation.

The only category of data that could be considered read only is the Libraries. The other categories all have update activity. Spool data tends to be almost half write activity. Key system control data is predominantly read. User data is usually predominantly read, but this varies from customer to customer. If the electronic store is non-volatile, the fraction of write activity is not a concern. The thing to note here is that only the libraries are suitable for a purely volatile store.

Figure 7 through Figure 10 show the comparison of static vs dynamic management for each of the four categories of consistently very active data at complex 53. The percent of total non-paging I/O that is captured in the electronic store is shown on the vertical axis. This axis is scaled the same in all four graphs. The MB of storage is shown on the horizontal axis. This axis has the same scale for key system and library data, but goes to much higher amounts of memory for the user and spool categories.

---

1 In the section on the application of the analysis to non-volatile cache compared to a solid state device (SSD) realistic assumptions are made for these devices and some of the consistently very active data sets are removed from consideration.

2 In the more realistic analysis of cache vs SSD the amount of variation seen in the afternoon sample will be discussed.

3 The authors would like to acknowledge the extensive help provided by J.S. Hyde, the developer of the IBM Cache Analysis Aid, in making the analysis in this paper possible.

4 In the analysis of cache vs SSD assumptions are needed and made about read to write ratios.

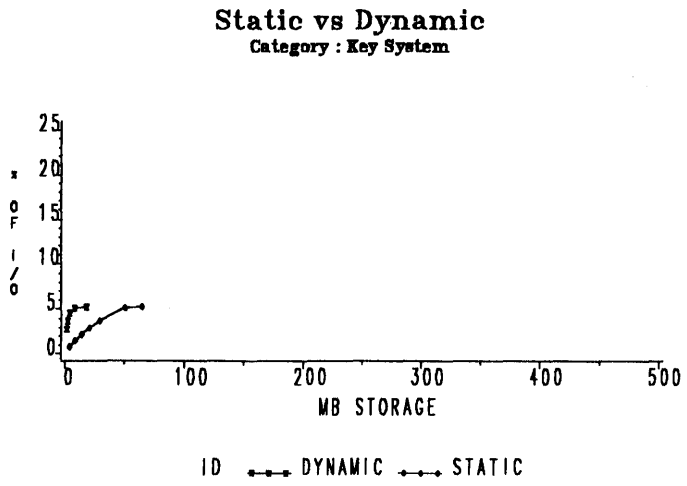

Figure 7. Static vs Dynamic Management for Key System Data

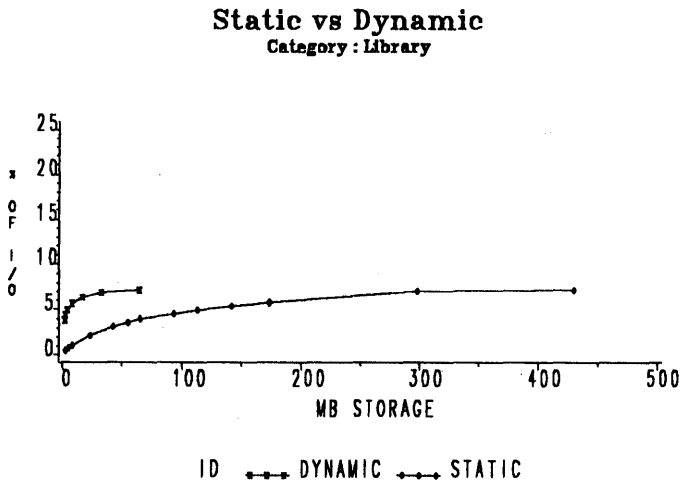

Figure 8. Static vs Dynamic Management for Library Data

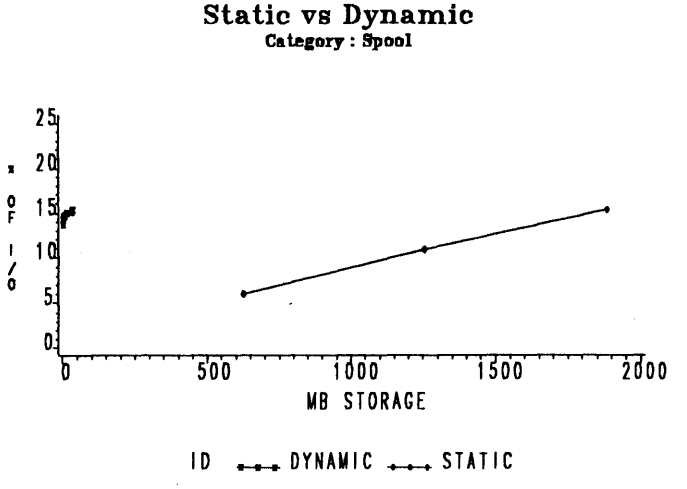

Figure 9. Static vs Dynamic Management for Spool Data

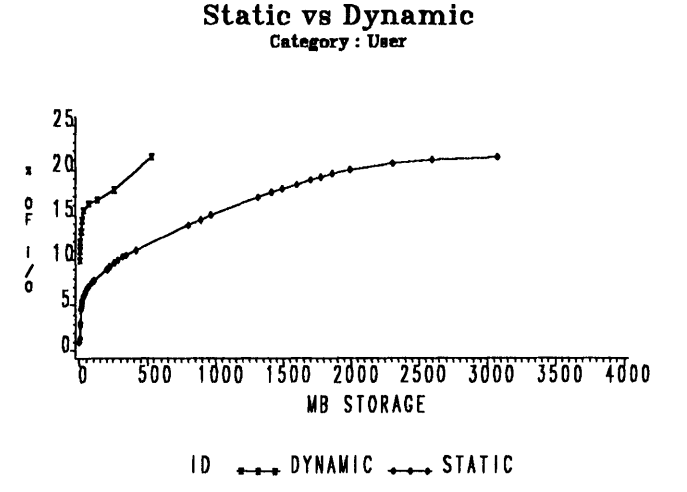

Figure 10. Static vs Dynamic Management for User Data

The dynamic management of the consistently very active data sets was better than static management in all four categories. Much less memory was required to handle the same amount of I/O at memory speed when the memory was dynamically managed. One reason for this is that, even over a time period as long as 15 minutes, the total number of bytes referenced in a data set is much smaller than the total number of bytes allocated to the data set. Another way of looking at these results is to note that for the same amount of memory, the dynamically managed data provided a much higher fraction of the total non-paging I/O at memory speed than did the statically managed store.

Application of Analysis to Cache vs SSD

Motivation

The above analysis provides some insight into the locality of reference of different categories of very active data, but does not make it easy for an installation to evaluate the relative effectiveness of a cached control unit and solid state device (SSD). It is not practical to place only consistently very active data sets under a cache. In practice an installation is more inclined toward placing whole volumes of data on a cache control unit. Furthermore, SSD is expensive; it is not realistic to put all the consistently very active data sets in SSD.

Spool data sets in particular have a low return on investment. They are too large for their I/O rate to be cost effective in an SSD, and have too low a read to write ratio to cache effectively on cache control units with volatile memories in spite of their good locality of reference. It is not even clear that speeding up the spool data set I/O would improve customer perceived performance. Thus, it seems that a customer would not seriously consider spool data sets for any kind of electronic store. Similarly, IMS logs are not good candidates for cached devices because of the predominance of write activity. They are not good candidates for SSD because of their size.

VTOCs are a special case of consistently very active data. They must remain on the volume with the data sets they point to. It does not make sense theoretically to place several VTOCs on an SSD. Thus, VTOCs were not considered as candidates for SSD.

Even with spool, IMS logs, and VTOC data eliminated from consideration, some customers have more consistently very active data than can realistically be placed on an SSD. Usually, the least I/O intensive of this data is some portion of the user data category.

A modified analysis was undertaken that was designed to reflect customer requirements realistically. Because the customers varied considerably in the fraction of non-paging I/O that goes to very active data, a form of normalization was introduced to facilitate the generalization of conclusions.

Analysis Method

The process of determining the SSD candidate data sets began with including the consistently very active data sets of all categories except spool. Then, in addition to spool data sets, the IMS logs and VTOCs were eliminated for the reasons outlined above. The SSD was assumed to be a non-volatile electronic store, so data sets with update activity were included as SSD candidates. Some installations had replicated IMS program libraries. These were aggregated by accounting for all of the I/O, but accounting for the space only once. In other words, only one volume was cached and only one copy of the data set was placed in the SSD, but all of the I/O was assumed to go to the one copy.

The criterion used to place data sets into the Solid-State Disk was based on access density (IOs/SEC/MB). The data sets with higher access densities were put into SSD first, until accumulated allocated space was over 2000 MB (a reasonable limit for SSD). The data sets that fit within the 2000 MB limit formed the set of SSD candidates.

In the case of cache, entire volumes were placed under the cache as opposed to only the SSD candidate data sets. Any volume that contained one or more of the data sets that would go into the 2000 MB SSD was placed on a cache control unit. The VTOCs associated with these cached volumes were of course cached. The cache was assumed to have volatile memory, and the cache management algorithms were assumed to be those of the 3880 Model 23.

Performance of the cache control unit was compared to the performance of the solid state device based on the amount of I/O that was handled out of the memory for components with equal memory and also for equal cost. The I/O handled out of the SSD was the total I/O to those data sets that would fit in the particular amount of SSD memory.

The amount of I/O handled out of the cache memory was the total I/O rate to all of the cached volumes, times the hit ratio, times the fraction of the I/O that were reads. Since the GTF traces used for cache analysis contained no CCW information, the read hit ratios are not exact and some assumptions need to be made about read to write ratios. In a separate calibration study several GTF CCW traces from some customers not included in this study were used to obtain overall hit ratios and read hit ratios. For all practical purposes the two hit ratio measures were the same. The overall hit ratios determined in this study from the SIO traces were used with confidence to predict the read hit ratios. Read to Write (R/W) ratios needed to be estimated from data collected for other studies. The studies described in the Washington Systems Center Technical Bulletin, IBM 3880 Model 23 Performance Measurements (order number GG66-0223) published in January of 1986, were used to estimate the read to write ratios for the categories of data evaluated here. The program library data sets were read only. The key system data sets had very high read to write ratios and user data tended to have R/W ratios of around 6:1. A ballpark estimate of an overall R/W ratio of 9:1 was chosen for the data considered in this analysis.

Results

The first set of results shows how much of the total non-paging activity on each system goes to 1) the SSD candidate data sets and 2) the volumes on which SSD candidate data sets reside. This information is needed in order to keep a perspective on what fraction of all I/O is being evaluated for management in some type of electronic store, and how this fraction varies depending on the type of installation. The leftmost set of bars in Figure 11 shows the percent of total non-paging I/Os that went to the SSD candidate data sets (solid part of bars) and to the cached volumes containing those data sets (total bar height). Each bar represents a different customer complex. With the SSD candidate selection used, about 17 to 45 percent of the non-paging I/O went to data that would fit into a full 2000 MB SSD. The percent of non-paging I/O that would go to the cached volumes ranged from about 20 to 60. The variation was due to the type of workload. The customers on the low end of these ranges were TSO environments where there were virtually no consistently very active user data sets. The customers with the higher fraction of I/O going to the SSD candidate data sets generally had production on-line application data included.

The rightmost set of bars shows the percent of the total non-paging DASD space allocated to the SSD candidate data sets (solid part of bar), and to the volumes under the cache (total bar). The variation here is due for the most part to the total number of volumes that needed to be included in order to account for all of the SSD candidate data sets.

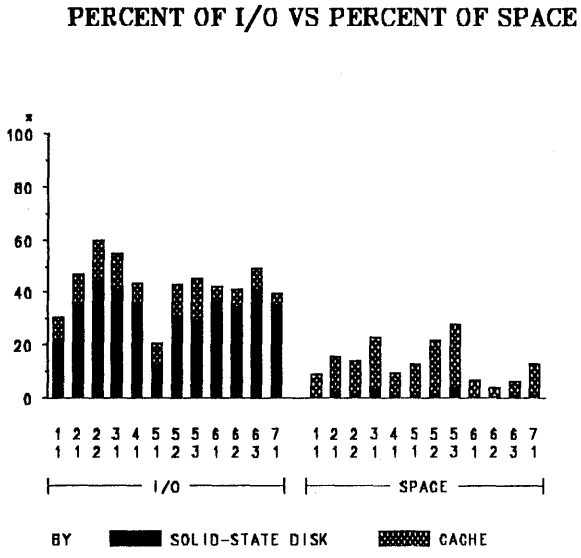

Figure 11. Percent of I/O and Space

The amount of I/O handled by a solid state device of increasing size is shown in Figure 12. Each customer installation is shown with a separate line on the graph. The graph has been normalized so that the vertical axis value of one represents all of the I/O going to the SSD candidate data sets. Recall from Figure 11 that this amount of I/O is a different fraction of total non-paging I/O for each installation. For all customers the curve rises steeply at first and then levels off as data is put into the SSD that has less return on investment.

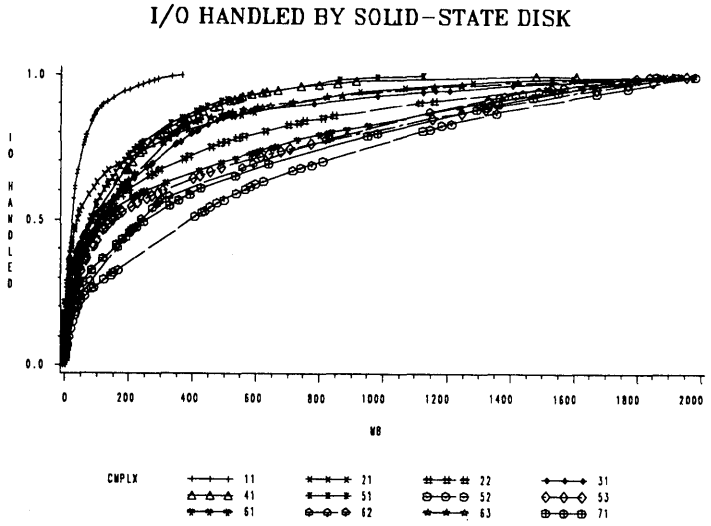

Figure 12. I/O handled by the Solid-State Disk for Each Complex

The issue of variability in the I/O rates was raised in the earlier discussion of static vs dynamic management of all of the consistently very active data sets. An analysis was done on the variability in the I/O rates to the SSD candidate data sets. The afternoon trace was analyzed to determine what I/O rates occurred to the data sets that were chosen to go into the SSD based on the morning traces. The percent of all non-paging I/O going to the SSD candidate data sets in the afternoon was calculated as a function of SSD size. The data sets were still assumed to be packed into the SSD in the order derived from the *morning* traces.

Figure 13 shows the results for the three TSO intensive complexes, and Figure 14 shows the results for three of the IMS customers. A subset of the customers is shown for example. The vertical axis shows a simple percent of non-paging I/O going to the data sets that fit within the SSD memory size shown on the horizontal axis. The solid line shows the morning percent, and the broken line shows the afternoon result. The three TSO customers vary little from the morning to the afternoon. Two of the customers obtained a higher percent of their I/O out of the SSD during the afternoon sample and one obtained a lower percent. The average change in percent of non-paging I/O for the TSO customers was .3 percent more I/O in the afternoon sample. The IMS customers varied more than the TSO customers. Note that these customers have more user application data in their SSD than the TSO customers do. The three customers shown in Figure 14 are the best IMS case, the worst IMS case, and one in between. The overall average change in percent of non-paging I/O for the IMS customers was 7.1 percent less I/O captured in the afternoon.

This sample is too small to draw sweeping conclusions. There appears to be no significant variation in the fraction of I/O handled by the SSD in TSO environments. In IMS installations, the variation averaged 7.1 percent and in one case was as much as 15 percent less I/O for the afternoon sample. It appears that key system and library data sets have consistent enough I/O rates from one time of day to another that an SSD optimized from one trace is likely to remain reasonably well optimized. On the other hand, on-line application data that is consistently very active still appears to have a lot of variation in I/O rates from one time of day to another. An SSD that is optimized for one time may yield less I/O during another time. In this analysis we are optimizing the placement of data sets in the SSD using the morning sample. Since we also use the I/O rates from the morning sample to compare the performance of the cache and the SSD, we are giving the SSD the benefit of the doubt about I/O rate variability. In customer sites where on-line application data resides in the SSD, the SSD may perform less well than is shown in this analysis.

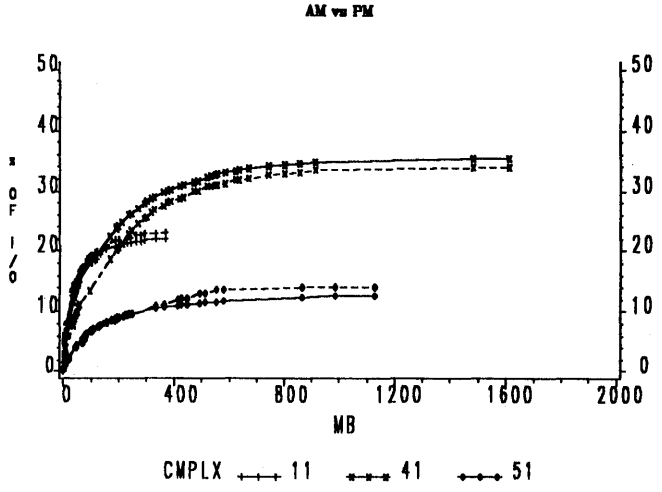

Figure 13. AM vs PM Activity for TSO Complexes

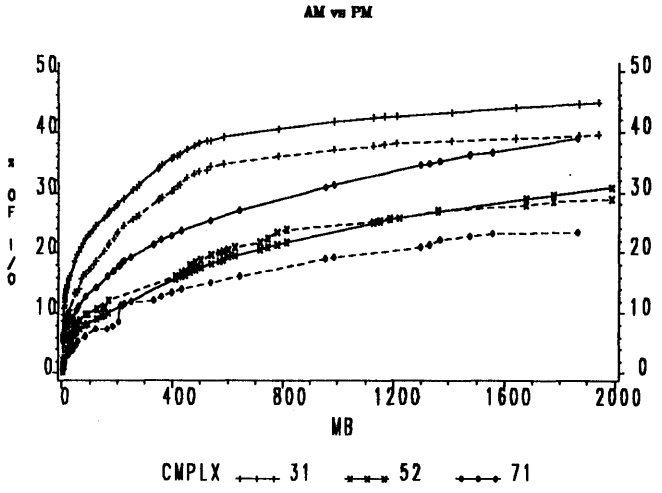

Figure 14. AM vs PM Activity for IMS Complexes

Figure 15 shows the amount of I/O handled out of increasing amounts of cache memory. For memory sizes over 64 MB, assume that more than one 3880-3 control unit was upgraded to a 3380-23. In most customer installations about 64 MB of cache provided most of the available benefit. The vertical axis is normalized in the same way as in the Figure 12: the value of one represents the amount of I/O that could be obtained out of a 2000 MB SSD. The fact that there is more data under the cached control unit than there is on the SSD allows the amount of I/O handled by the cache to go over the value of one. The fact that not all I/Os are read hits tends to drive the number down. All but one customer was able to handle at least as much I/O from a moderate amount of cache memory as was handled by a 2000 MB SSD. The range was from about 80 percent to 150 percent of the SSD I/O.

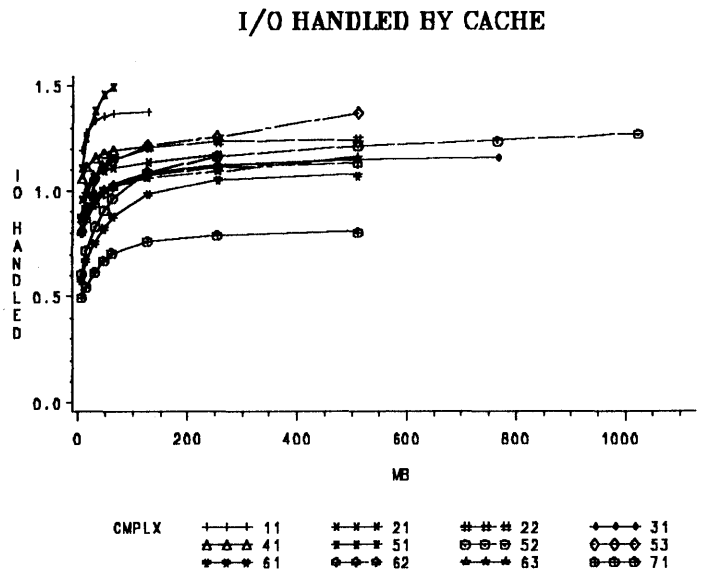

Figure 15. I/O handled by the Cache for Each Complex

If each installation's SSD curve from Figure 12 were paired with the respective cache curve from Figure 15, the SSD curve would fall under the cache curve. In other words, for the same amount of electronic memory, the cache is able to handle more I/Os out of the cache memory than are handled out of the SSD. Figure 16 shows the average cache curve and average installation SSD curve. At 64 MB of memory, the cache control unit handles about 2.5 times more I/O at electronic speed than the SSD does. At about 200 MB of memory, the cache handles about 1.75 times more I/O at electronic speed than the SSD does.

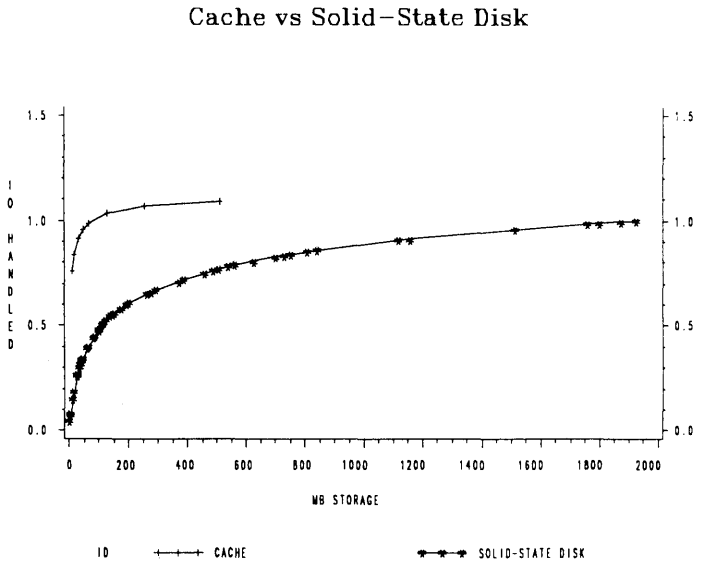

Figure 16. I/O handled by Cache and SSD for Equal MB Comparison

The more interesting question, of course, is how do the cache and SSD compare on an equal cost basis. The starting point for addressing this question is to make some cost assumptions. Prices change in time and vary with circumstances. Pricing assumptions used in this analysis are for illustration and are somewhat arbitrary; the numbers should be adjusted to reflect other situations. It was assumed that the cost of the cache would be the cost for the MES upgrade of a 3880-3 control unit to a 3880-23. This makes sense since there would be no need for additional control units, only the adding of cache to one or more existing control units. The price used for the MES upgrade was $321,130 dollars for the 64 MB unit. The 8 MB upgrade was priced at $69,130 dollars. Upgrades between 16 and 64 MB were base priced at $33,130 plus $72,000 for each 16 MB increment. Price assumptions for the SSD were more arbitrary since there is a range of prices depending on vendor and discount. The prices used reflect an example of prices for non-volatile SSDs that are heavily discounted from their list prices. The example price includes both controller and memory. An entry level system was assumed to be 64 MB and to cost $195,000. Memory increments over the base system were priced at $1,000 per MB. The maximum single unit was assumed to be 512 MB for a cost of $643,000.

If these cost assumptions are applied to the MB of storage given in Figure 16, then the I/O handled can be shown as a function of the cost. Figure 17 shows the I/O handled out of cache memory and the I/O handled out of SSD with cost on the horizontal axis. The entry level cost for the cache is less than the cost for an entry level SSD, and the cache handles almost twice the I/O handled by SSD system. If the chart is examined to determine a point that might be considered optimal for the cache and a point that might be considered optimal for the SSD, a cost of about $300,000 comes to mind. Beyond this point both types of devices offer little return on investment. A $300,000 investment would yield about 1.7 times more I/O out of the cache than out of the SSD.

In summary, when reasonable assumptions are made about data to put into an SSD and how to get the same data under a cache control unit, the cache solution looks better. The cache handles about twice as much I/O out of a reasonably sized cache as the SSD does with a similar amount of memory. The same I/O rate out of cache can be obtained with a *much* smaller memory size than would be needed for an equivalent I/O rate out of the SSD device. A comparison of the cache and SSD performance based on equal cost configurations also shows the cache to be the better solution. At configurations of about $300,000, the cache handles about 1.7 times as much I/O out of memory than the SSD does.

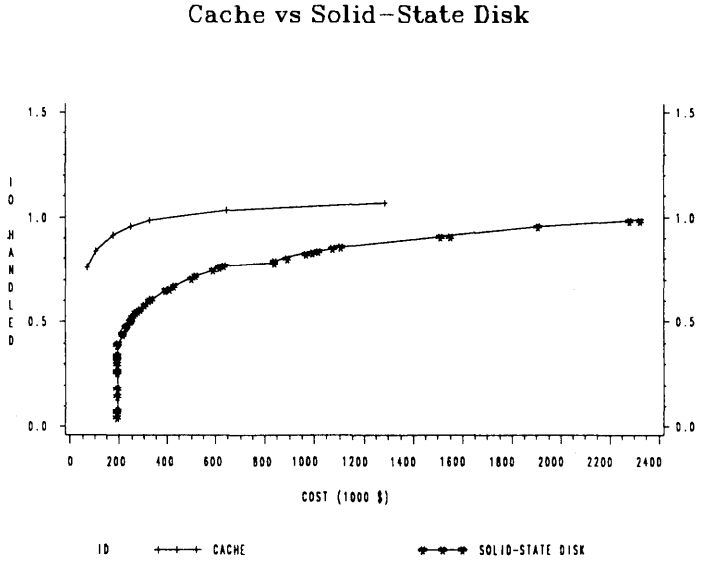

Figure 17. I/O handled by Cache and SSD for Equal Cost Comparison

Conclusions

- The consistently very active data sets in the customer complexes studied were responsible for about 25 percent to 70 percent of the non-paging I/O on the system. There was less I/O to this type of data in TSO installations than was seen in IMS or CICS dominated installations because of the absence of on-line application data that is active every day.
- Libraries and key system control data sets had the highest I/O rates for the amount of storage they occupied. Spool data and some user application data were consistently very active, but less I/O intensive.

- Libraries, key system data and spool data had a higher locality of reference than user application data.
- Libraries were the only category of consistently very active data that were read only. Spool data in particular has a low read to write ratio.
- All four categories of data had good enough locality of reference that a dramatic advantage was seen in managing this data dynamically rather than statically.
- When the subset of the consistently very active data sets that are suitable for placement in a Solid State Device (SSD) was selected, they accounted for about 17 to 45 percent of the non-paging I/O on the system.
- The volumes containing the SSD candidate data sets had I/O rates that accounted for about 20 to 60 percent of the non-paging I/O on the system.
- For reasonably sized cache and reasonably sized SSD, the cache control unit handled about twice as much I/O out of cache memory as was handled out of the SSD memory.
- For an equal cost cache and SSD, the cache control unit handled about 1.7 times more I/O than was handled by the SSD.

A Simulation Model for Determining Optimal Freespace Levels on MVS Disk Storage Volumes

Kenneth E. Levy
Mobil Administrative Services Company Inc.
P. O. Box 1033
Princeton, New Jersey 08540

ABSTRACT

Freespace within MVS disk storage pools is a necessary evil. Without the proper amount of freespace, users will be subjected to application failures due to lack of disk space. This paper describes a simulation model for determining the cost/benefit tradeoff for maintaining various levels of freespace on MVS disk storage volumes. Economically sound policies for freespace levels can then be derived from the results.

INTRODUCTION

Elimination of private disk ownership and establishment of system managed pools of disk space is justified for the labor savings derived from having the computer automatically control and maintain storage[1]. Pooled storage does pose new problems and costs, however. Instead of humans allocating and scratching datasets and manually controlling freespace, the system must perform this function. For new datasets, the system performs this function quite well. The system will automatically search all volumes in a storage pool to locate a volume with sufficient space to satisfy the request. Finding space for secondary extents for existing datasets, however, presents a problem. These requests must be satisfied from freespace on the volume on which the data set resides. Thus, freespace must be maintained on volumes to minimize the number of abends due to dataset extension failures. The storage administrator is faced with the question of the optimal level of freespace to be maintained on an MVS storage volume? Is it ten percent? Twenty percent? Or is it even larger? Clearly it is not cost effective to maintain disk space which is never used. It is also uneconomic to reduce freespace to a level which generates abends (due to cost of reruns for failed applicatiosn). This paper will present a method for solving the optimal freespace problem.

ANALYTIC MODEL SOLUTION

Initially, an analytic model was proposed to address this question. It was thought that if the extent size frequency distribution could be fit to a curve, a probability function could be derived to determine the probability of allocation failure for any given level of freespace. Unfortunately, when the size frequency distribution was examined (Figure 1), it presented several problems. First, it was impossible to fit a smooth curve to the distribution function. There were spikes in the curve at regular intervals (15 tracks, 30 tracks, 45 tracks, etc.). These spikes generally represent datasets allocated in units of cylinders rather than tracks. A second, third, or higher order equation could have been fitted to handle these discontinuities. However, this presented several new problems. Each pool, with its corresponding frequency distribution, would have to be fit with its own function. If a large number of pools were to be examined, the effort required would be considerable. Also, this method presents difficulties if there is an irregular pattern of spikes. For example, allocations could be bunched at one, five, and ten cylinders, but not at intervening cylinder boundaries. These are typical of allocation quantities "guesses", where the exact amount of storage was not pre-calculated. This form of model was finally rejected due to lack of a "general" solution which would fit all forms of frequency distributions (pools).

SIMULATION MODEL SOLUTION

A simulation model seemed to present a logical next step for tackling this problem. If the allocation / scratch process could be simulated by a program, the number of allocation failures could be counted and the probability of failures at various freespace levels could be calculated and plotted (Figure 2). The optimal freespace can be then be determined by simply inspecting the plots to determine the level of failures acceptable to a particular installation.

The simulation program which models the allocation / scratch process on the simulated volume is rather simple. Two lists are maintained, the first representing allocated extents on the volume, and the second representing freespace extents on the volume. Initially, the allocated list is empty, and the freelist contains one entry reflecting the total number of tracks contained on the simulated volume. As datasets are allocated, entries are added to the allocated list and the entries in the freespace list are manipulated, much like the FORMAT5 DSCB's on a MVS volume's VTOC.

To simulate reality, the sizes of allocated extents within an actual dasd pool were used to generate simulated data sets with the same size frequency distribution within the model. This was accomplished by converting the size frequency distribution (Figure 1) into a cumulative frequency distribution (Table 1). The number of tracks to be allocated for each simulated dataset is determined by using a random number to index into the cumulative percent column.

Cumulative Frequency Distribution

Tracks	Frequency Percent	Cumulative Frequency Percent
1	46.7008	46.7008
2	10.7002	57.4011
3	4.1500	61.5510
4	2.3394	63.8904
5	5.7170	69.6074
6	1.3139	70.9213
.	.	.
2655	0.0032	99.9968
3300	0.0032	100.0000

Table 1.

TSO POOL

FREQUENCY BAR CHART

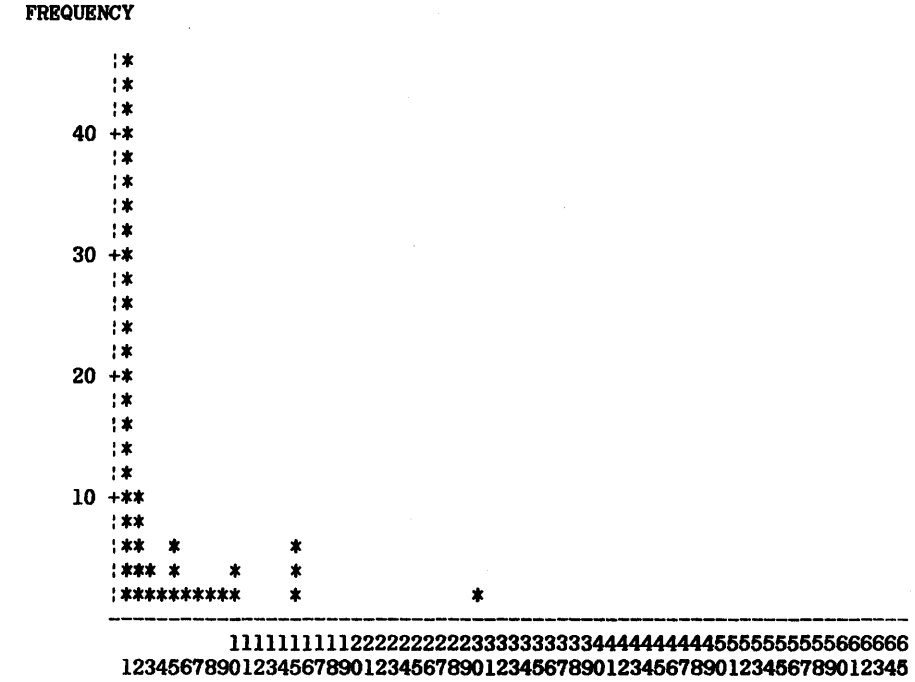

Figure 1.

TSO POOL

Plot of FAILPROB*PCALLOC Legend: A = 1 obs, B = 2 obs, etc.

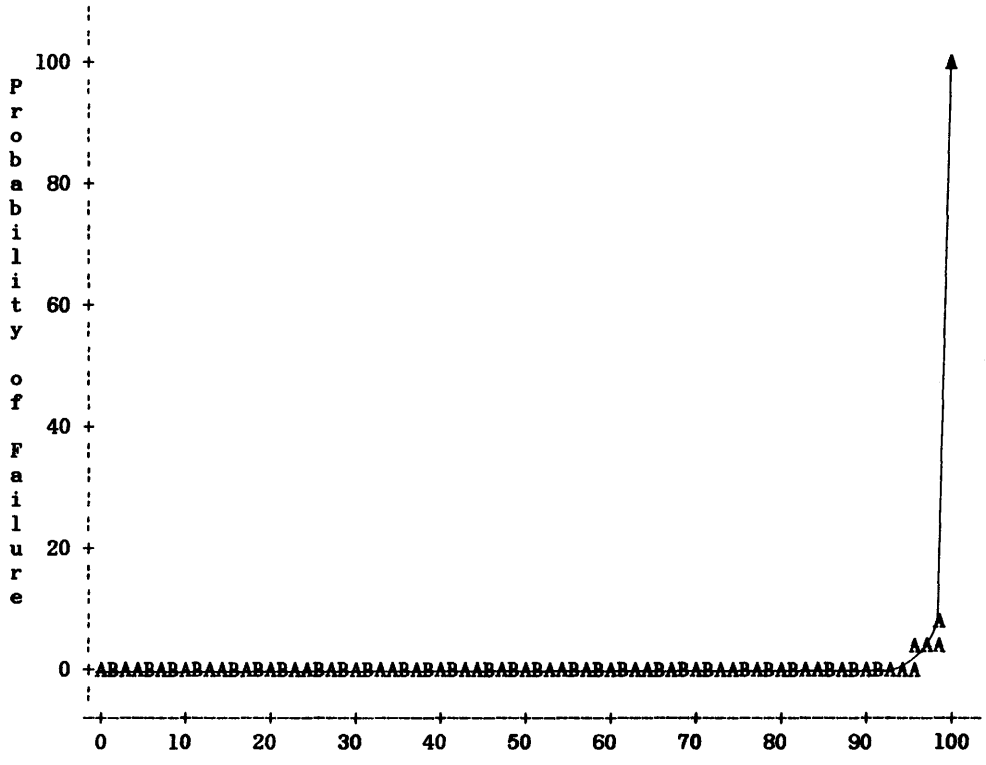

Figure 2.

To simulate the allocation of a dataset extent, a random number is generated between zero and one hundred percent. The cumulative distribution table is then scanned until the corresponding percentage is reached. The extent size that corresponds with that cumulative frequency will be used in the attempted allocation. As more and more datasets are allocated on the simulated volume, the frequency distribution of sizes on the simulated volume will closely correspond to that of the original pool. Parameterization of the simulation model for an existing pool of disks becomes simply a task of mapping the existing dataset extents on the volumes and converting the map into a frequency distribution. This makes parameterization of the model extremely simple for virtually any disk pools.

The simulation model was written in approximately 650 lines of MICROSOFT QUICK BASIC code, of which approximately one third are comments. The input to the model consisted of the cumulative frequency distribution curves, enhanced by the addition of cylinder allocation and unmovable attribute probability measures for each extent size. These last two items were used to more closely approximate the actual allocation process.

The allocation / scratch process was simulated completely in memory with no I/O required until the completion of the simulation run. The freespace on the simulated volume was varied from a target level of one percent to ninety nine percent (the endpoints of zero, where all allocations should fail, and one hundred percent, where no allocations should fail, are known). At each target level, datasets were allocated until the target freespace was reached. The success or failure of the allocations done during this "run-up" to the target level was not recorded. After the target was reached, one thousand allocations were attempted. After each attempt, the success or failure (due to space unavailable) is recorded. Datasets were then randomly deleted (if required) to back the volume down to the target freespace level. The number of allocation failures was accumulated in a matrix for conversion to a percentage and printing when all freespace levels had been simulated. The final output consists of the target freespace percentage and the probability of failure (number of failures divided by the number of attempts) at each level.

RESULTS

The model was run for three different frequency distributions reflecting three pools found at on large data center sharing disks between a complex of three 3090-200 processors. Several statistics were derived to help characterize the datasets within each pool (Table 2).

POOL	MEAN SIZE (tracks)	MEDIAN SIZE (tracks)	95%-tile (tracks)	STD DEV. (tracks)
TSO	11	2	45	56
BATCH	33	8	120	139
RESERVED	46	2	129	253

Table 2.

Each pool was simulated separately. Combined, the runs took approximately twenty-three hours of CPU time to run on a 6-Mhz IBM PC/AT with 640K memory. No extensive optimization or tuning of the model was performed. The frequency distributions and model results for each pool are presented in Figure 1 through Figure 6. They results are also summarized in table three.

	Percentage Freespace to be Maintained		
POOL	Probability of Failure < 1 %	Probability of Failure < .5 %	Probability of Failure 0 %
TSO	10 %	14 %	18 %
BATCH	22 %	27 %	48 %
RESERVED	25 %	28 %	56 %

Table 3.

It should be noted that for the pools with numerous large datasets, relatively large amounts of freespace are required to reduce to a zero percent probability of failure for allocations to that pool. This suggests that 'very large' datasets should be segregated from the small datasets. A relatively small amount of freespace would have to be maintained in a small dataset pool to minimize allocation failures.

CONCLUSION

A simulation model for determining optimal levels of freespace has been described. The model provides an approach that is easily adaptable to a large variety of dasd pools.

NEW MEASUREMENT DATA SOURCES FOR MVS X/A AND ITS SUBSYSTEMS

H. W. Barry Merrill, PhD
Merrill Consultants

ABSTRACT

Since MVS/XA 2.1.0 became available in 1984, IBM has made significant changes in MVS/XA software and hardware architecture. New data exist to measure and manage these enhancements. SMF/RMF measurement of the vector processor, extended storage and the 3090 I/O processing enhancements will be discussed. Additional enhancements and the incompatible changes that have been announced in MVS/XA 2.2.1 will be described.

OVERVIEW

1. TYPE 70 CPU DATA
2. VECTOR FACTILITY MEASUREMENT
3. TYPE 71 EXTENDED STORAGE ARCHITECTURE
4. TYPE 72 WORKLOAD MEASUREMENT
5. TYPE 74 DEVICE MEASUREMENT
6. TYPE 78 I/O FOR 3090
7. TYPE 78 VIRTUAL STORAGE
8. MVS 2.2 ANNOUNCEMENT
9. 1 MIPS 2 MEG

1. TYPE70

RMF CPU Activity

There have been several significant changes to TYPE70 since 1984.

What is a CPU? Originally, a CPU was the Central Processing Unit; for some time, we have had multiple CPUs executing under the control of one operating system, and they have been called MPs, Dual Processors, APs, Dyadics, Triadics, Quads, IPL and non-IPL, and so forth. In some papers, this author has used the term multi-engine system to describe these complexes in which more than one CPU is under the control of a single copy of the operating system. Recently, IBM has introduced another term, the Central Electronic Complex (CEC), to describe the physical hardware that contains one or more CPUs (processors, engines) under the control of a single copy of the operating system. Take your pick, and take your chances!

The 3084 CPUs were numbered zero through three, but the 3090-400 are numbered one through four, and the 3090-800 probably will be numbered one through eight. Now, there are nine groups of CPU-specific variables, suffixed 0 through 8.

MVS 2.1.7 reversed the order in which Test Pending Interrupts (TPI) I/O is serviced. Formerly, TPI interrupts were serviced from low to high CPU number; now, the selection for handling TPI is from high to low CPU number. The TYPE70 I/O interrupt rate on 3090s is somewhat higher (5%?) than the TYPE78IO IOP activity rate. The difference may measure I/O redrive requests.

The recursive scan of the dispatcher queue before entry into the wait state, the primary cause of the low utilization effect discussed on page 98 in [1], has been significantly reduced. Instead of scanning all address spaces (including logically swapped ASIDs), the MVS 2.1.3 dispatcher scans only address spaces in memory. MVS 2.1.7 eliminates the recursive scan entirely, which has produced a measurable reduction in uncaptured CPU time. See CPUOVHTM in the RMFINTRV section of Chapter 40 in [2].

1.1 SERVICE UNITS PER SECOND

The Service Units per second value (SU_SEC, also called the Machine Dependent Constant, MDC) is now contained in the type 72 record. The table look-up in VMAC7072, which set SU_SEC from CPUTYPE and CPUVERSN, is not used after RMF 3.3, and updates to VMAC7072 with each new processor are no longer necessary. The importance of SU_SEC is unchanged, and its value can still be determined; see [1], pp 686-687.

Because the SU_SEC is derived by IBM from benchmarks (analyzed with you know who's software), the value has proven to be an excellent estimate of the processor capacity prior to the availability of actual hardware benchmarks for your own workload. A major source of confusion, however, is the apparent inconsistency in SU_SEC values between processors. For example, the SU_SEC for a 3081KX is 399, but a 3084QX value is 373.8. Since a 3084QX is simply two 3081KX's, why are they not equal? The reason is that the purpose of the MDC is to make CPU service units consistent.

When benchmarks show that a four-engine CEC records more seconds of task CPU time (type 30) than the same task recorded for a two-engine CEC, the MDC of the four-engine CEC must be smaller than the value for the two-engine CEC. The CPU time (TCB, SRB, and even uncaptured) is larger for a task in a dyadic than for one in a uni-processor. CPU time is accumulated while a task is executing, and if the task needs data that are not in cache storage, the task's CPU time continues to accumulate while the CPU competes with other CPUs for storage control. The competition (and therefore the measurable increase in CPU) grows with the number of engines. In actuality, the SU_SEC value is a single constant for an engine, and RMF de-rates the constant based on the number of engines currently on-line:

Table 1. Processor derate factor versus number CPUs

Processors on-line:	1	2	3	4	5	6
RMF 2.1.3 derate	100%	93%	88%	85%	80%	76%
Prior derate	100%	95%	92%	89%	-	-

An additional complication is the confusion of CPU speed with CPU capacity. In the preceding example, the 3081KX with a speed of 399 SU_SEC has two processors for a capacity of 798 SU_SEC, while the 3084QX speed of 373.8 provides a service unit capacity of 1495.2 per second. The following table provides both the speed and the capacity in raw service units for many IBM processors.

Table 2. CEC CPU "Speed" and "Capacity" values

CEC Model	MDC Speed	SU_SEC Capacity
155	42	42
168	151	151
3033U	261.3	261.3
4381-R14	200.6	401.2
3083JX	420	420
3081KX	399	798
3084QX	373.8	1495.2

CEC Model	MDC Speed	SU_SEC Capacity	CEC Model	MDC Speed	SU_SEC Capacity
3090-150	451.6	451.6	3090-150E	471.9	471.9
3090-180	750	750	3090-180E	823.5	823.5
3090-200	712.5	1425	3090-200E	765.9	1531.8
			3090-300E	724.7	2174.1
3090-400	667.5	2670	3090-400E	700	2800
			3090-600E	625.9	3755.4

As with any set of numbers, use these with caution. Recognize that they are aimed at maintaining consistency of service units for typical work and will not always apply to all processors or all workloads. Only an actual benchmark of your workload on your processor will provide exact measures.

1.2 ASID Count by State

These measures [1], pp 687-688, are good indicators of the overall system health, and they can specifically indicate constraints on the multiprogramming level (MPL) that can result from incorrect specification of MIN/MAX MPL values for each domain. Thanks to Bill Mullen's 1986 CMG presentation for the following guidelines:

READYAVG (the average number of IN and READY address spaces) should be less than 10% of INAVG. A too-high percentage of IN memory ASIDs is one result of specifying an MPL that is too high, which can cause significant queueing delays waiting for CPU dispatch. The suggested 10% value will maintain a queue (so the processor is not idle), but the delay will be small.

OUTAVG (the average number of OUT and READY address spaces) should not be greater than one for each active CPU engine. A higher value indicates a constraint on domain MIN/MAX values that could be examined by tracing (TYPE76) domain utilizations or by the display domain operator command.

LRDYAVG (the average number of LOGICALLY OUT and READY address spaces) should be zero. Like OUTAVG, it indicates possible domain constraints.

2. Vector Facility Measurement

The optional vector facility is described by its on-line status (VFONn) and the affinity duration (VFAFFTMn) for each CPU engine.

Vector facility affinity time is the duration of CPUTCBTM accumulated for all tasks having affinity to the vector processor. It is captured separately for each CPU engine. When a task first uses a vector instruction, it is given affinity to only the processors that have the vector facility. It keeps this affinity until the dispatcher detects that vector instructions have not been used for a long time. (A long time is 50 milliseconds of TCB with no vector instruction.) A task that has lost its vector affinity because of non-use can regain affinity when it again issues a vector instruction. Vector affinity time, VFAFFTMn, is accumulated for each engine that has a vector processor only when a task with vector affinity is dispatched and is executing under its TCB in that engine. Only one task can accumulate VFAFFTMn at one time in one engine, although several vector tasks can be waiting to be dispatched on that same engine.

Affinity time should be used for capacity planning and cost recovery of the vector processor. There is no more vector facility capacity when those engines with a vector processor record 100% affinity time. Because affinity time is a part of CPU TCB time, 100% affinity time occurs when VPAFFTMn equals CPUTCBn and the processor is 100% active. CPUTCBn is not directly measurable (except on a UP), but MVS uncaptured CPU time and SRB CPU time cause the measured VPAFFTM at 100% capacity to be significantly less than 100% of DURATM.

Vector affinity time is also accumulated by step in the TYPE30_4 and TYPE30_5 data set variables VPIAFFTM and VPUAFFTM. Two additional step level variables, VPIUSETM and VPUUSETM, describe the duration of actual vector processor execution within affinity time. See the TYPE30 section in Chapter Forty in this supplement.

For additional reference material on the vector facility, see Paul Dorn's excellent Washington Systems Center technical bulletin, "MVS/SP 2.1.3 Vector Facility Enhancement Overview," LG66-0227-00, and the "3090 Vector Facility Technical Reference," GG24-3058-0.

3. TYPE71

3.1 RMF Paging and Swapping Activity

The existence of extended memory (originally named expanded memory) has made significant changes in the TYPE71 data set, especially with swap counting and swap possibilities. With MVS 2.1.3 or later and on a 3090 processor with extended memory, Figure 1. describes the the possible swap states and their transitions.

The four boxes in Figure 1 are the four states in which a swappable task can be found. The six vectors indicate the possible transitions that a task can follow among these four states. The letters in parentheses and the phrases in quotes describe in which report column (see below) RMF prints these swap rates. The names in uppercase are the prefixes of the MXG variables that measure the transitions.

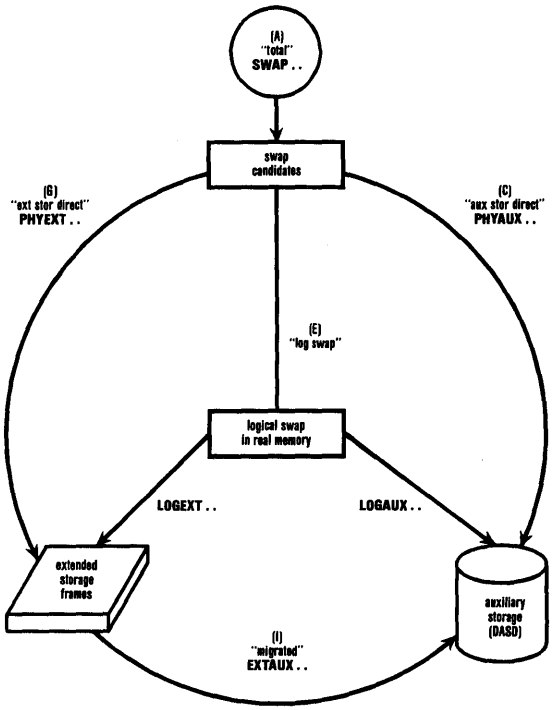

Figure 1. All Possible Swap States and Transitions

SWAP.. -- swap candidates count (rate per second)

Swap candidates will initially change state by one of the following three possible transitions:

PHYEXT.. -- physically swapped directly into extended storage

PHYAUX.. -- physically swapped directly to auxiliary (DASD) storage

logical -- logically swapped in real memory.

Tasks that are logically swapped in real memory (that do not become ready before the think time limit) could then undergo one of the following two possible transitions:

LOGEXT.. -- physically swapped from logical to extended storage

LOGAUX.. -- physically swapped from logical to auxiliary storage.

Tasks that have been moved to extended storage (that do not become ready before their extended storage space is needed) will go to only one state:

EXTAUX.. -- migrated from extended storage to auxiliary storage. (Pages migrated are moved to real storage and then moved to DASD.)

There are eleven reasons why a task may be swapped. These reasons are described on pages 715-717 in [1], by the SWAP.. variable names that end with the following swap reason code suffixes:

Table 3. Swap Reason Codes

blank - total for all eleven swap reasons
AS - auxiliary storage shortage (very unlikely)
DW - detected wait
EX - exchange on recommendation value
NQ - enqueue exchange
NS - transition to non-swappable (not many)
RS - real pageable storage shortage (very unlikely)
TI - terminal input wait
TO - terminal output wait
US - unilateral - SRM overcommitted or domain MPL exceeded
VR - request swap (not many)
WT - long wait.

These eleven reason codes (plus the total for all reasons) for each of the six possible transitions are stored in seventy-two swap rate (per second) variables.

The RMF swap placement activity report describes how SRM handles these swap requests and how effective SRM is in the way it satisfies these requests. Each row of the RMF report describes one swap reason. The following columns on the RMF report can be calculated directly from MXG variables:

Table 4. RMF Report Calculation Equations

Column and Heading on RMF Report	Calculated as
A total	= SWAP
B aux stor total	= PHYAUX + LOGAUX + EXTAUX
C aux stor direct	= PHYAUX
D aux stor via transition	= LOGAUX + EXTAUX
E log swap	= SWAP - (PHYEXT+PHYAUX)
F log swap effective	= SWAP - (PHYEXT+PHYAUX+ LOGEXT+LOGAUX)
G ext stor direct	= PHYEXT
H ext stor total	= LOGEXT + PHYEXT
I migrated	= EXTAUX
J ext stor effective	= LOGEXT + PHYEXT - EXTAUX
K log swap/ext stor eff.	= SWAP - (PHYAUX+LOGAUX+ EXTAUX)

Although all of these swap rate fields measure some facet of extended storage, the most important swap rate is EXTAUX, the rate of swapping migration. A low migration swap rate indicates that extended storage pages are not being moved to DASD, and the full benefits of extended storage are being achieved. (Although the EXTAUX transition is from extended to auxiliary storage, the actual physical pages first move to real storage, and are then written out to auxiliary DASD.)

The flow chart of Figure 2 was originally prepared by Dr. Jeff Buzen for the BGS User's Group meeting prior to CMG 86. It is presented here with appreciation and minor revisions. The chart follows the decision logic within MVS that determines which transits are actually taken. The letters identify the RMF report column.

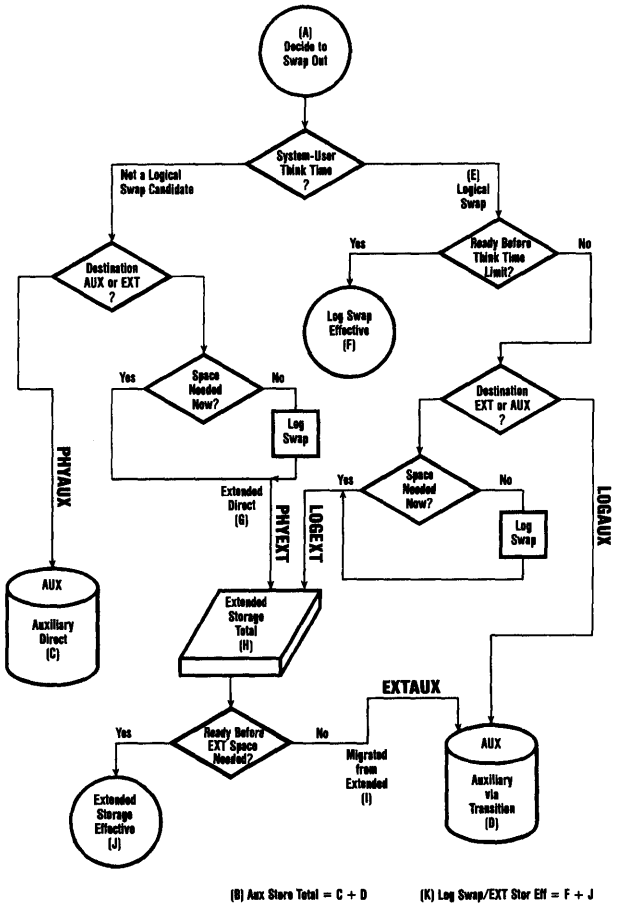

Figure 2. MVS/XA Extended Swap Decision Logic

The RMF paging activity report has changed somewhat as a result of the extended storage. The following figures identify which MXG variables are printed in which location on the RMF report.

Table 5. RMF Main Storage Paging Rates per Second

category	page reclaims non-swap	page in swap	page in non-swap	page out swap	page out non-swap
pageable system areas (non vio)					
lpa	LPARECLM		LPAGINS		
csa	PVTCAREC		PVTCAIN		PVTCAOUT
address spaces					
vio	PVTVAMR		PVTVAMI		PVTVAMO
non vio	PVTNPREC	PVTSPIN	PVTNPIN	PVTSPOUT	PVTNPOUT

All other columns on this RMF report are either sums or percentages of these thirteen values.

main storage frame counts number of samples NRSAMPLE

	min	max	avg

3.2 Extended Storage Paging Versus Swapping

The preceding discussions might lead you to believe that extended memory is only used by swapping, but that is not true. RSM, Real Storage Management, treats extended storage as an extension of real memory, and both swap and nonswap pages are moved from real storage to extended storage. By moving pages to extended storage instead of to auxiliary storage, a page-in can usually be avoided.

3.3 Control Mechanisms for Extended Storage

The Real Storage Manager (RSM) controls the utilization of extended storage by using a value called the criteria age to determine when a page should be sent to extended storage. The criteria age is specified by keywords in OPT for various types of pages and for three types of users. RSM then compares the selected criteria age value to the following two measures of real storage contention:

HIUIC:
System-high unreferenced interval count (UIC). This is the age in seconds that a page has remained unreferenced in real storage. A low value indicates contention for storage.

MIGAGE:
Migration age. This is the average age in seconds that pages have remained unreferenced in extended storage.

RSM wants to send to extended storage only those pages that are likely to be referenced again before being migrated to auxiliary storage. The decision logic depends on the type of page involved, and on the measures of HIUIC, MIGAGE, and think time:

Type of Page:	Sent to Extended Storage when:
Swap	HIUIC + MIGAGE > Criteria Age
Terminal Wait	HIUIC+MIGAGE-Think Time > Criteria
Stolen, Virtual Fetch, Page Out	MIGAGE > Criteria Age

The type of user is specified by the following keywords:

0=nonswappable, common, or privileged
1=all others not in type 0 or type 2
2=terminal wait swap, or TSO stolen or paged-out.

Based on both page type and user type, the criteria age is selected from the following table of defaults, which also summarizes the criteria test:

Table 6. Extended Storage Criteria Age

OPT Keyword	Page Type	Type of User Owning Page 0	1	2
ESCTPOC	Changed page-out pages	100	100	100
ESCTPOU	Unchanged page-out pages	100	100	100
ESCTSTC	Changed stolen pages	0	20	15
ESCTSTU	Unchanged stolen pages	0	20	15
ESCTSWTC	Changed swap-out pages	100	100	60
ESCTSWTU	Unchanged swap-out pages	100	100	60
ESCTSWWS	WKSET pages ready for swapout	100	100	50
"	Terminal swap pages		100	
ESCTVF	Virtual fetch pages		15	

Page Type	Criteria
Changed page-out pages	MA > CA
Unchanged page-out pages	MA > CA
Changed stolen pages	MA > CA
Unchanged stolen pages	MA > CA
Changed swap-out pages	UIC+MA > CA
Unchanged swap-out pages	UIC+MA > CA
WKSET pages ready for swap-out	UIC+MA > CA
Terminal swap pages	UIC+MA-TT > CA
Virtual fetch pages	MA > CA

3.4 Sequence of Swap Actions

When an address space that was swapped directly from real storage to auxiliary storage (PHYAUX and LOGAUX swaps) is to be swapped back in, ASM reads and writes these working set pages from DASD to real memory. This is called a single-stage swap-in.

If an address space is swapped from real storage to extended storage, RSM and SRM split the address space into primary and secondary working sets. The primary working set is the LSQA pages, fixed pages, and the first page from each virtual storage segment. (The first pages are necessary for reconstruction of the virtual segment and page tables at swap-in.) RSM manages the primary working set as one entity. The secondary working set is all other working set pages.

If the address space is later selected for migration to auxiliary storage, RSM migrates the secondary working set in groups, based on the need to replenish the extended-storage-available frame queue. ASM then writes these secondary working set pages as group requests to the page data sets. After the entire secondary working set has been selected for migration, the RSM swaps the primary working set from extended storage into real storage and then writes it out to DASD auxiliary storage.

Once an address space has been split, the RSM must return the entire primary working set to real memory before the address can become dispatchable. If the address space has been migrated, the primary working set is swapped first, and then the secondary working set is swapped. This is called a two-stage swap-in.

3.5 Extended Storage Measurements

Given the preceding discussion, the actual measurement of extended storage is simple. The most important measure of utilization is PGMIEXAU, the actual rate of page migration from extended storage to auxiliary storage. If there is no movement of pages from extended to auxiliary, then extended storage is clearly not overcommitted. To place page movement in perspective, however, PGMIEXAU must be compared (perhaps as a percentage) to PGMVTOEX, the total page movement rate

into extended storage. Note, however, that it is not possible to separate page movement or migration due to swap pages from page movement or migration due to nonswap pages. PGMVTOEX and PGMIEXAU disregard the type of page being moved when they count page movement.

In current 3090 architecture, pages to be migrated are actually moved first from extended storage to real storage, and then they are physically moved from real to auxiliary storage; but that design is likely to change.

If appreciable migration from extended to auxiliary storage occurs, only then is it worthwhile to determine which swap reasons are involved by examining the eleven EXTAUX.. variables. Note that these variables count the rate that address spaces are moved or migrated, rather than counting the rate that pages are being moved.

4. TYPE72 WORKLOAD MEASUREMENT

4.1 RMF Workload Activity

The SU_SEC value, page 686 in [1], is no longer acquired by table look-up from CPUTYPE and CPUVERSN in TYPE70. RMF 3.3 added the value of SU_SEC in the type 72 record. SU_SEC is of critical importance because it is used to convert CPU service units into CPU seconds in TYPE72. By then subtracting the TYPE72 control performance group CPU times from the TYPE70 CPU active time, the MVS uncaptured CPU time can be measured. This is done in the RMFINTRV data set, which is described in Chapter Forty in [2]. SU_SEC also identifies the speed of the processor engine, which is important for capacity planning, and permits normalization of processor measurement for machines of different speed. See the new section on service unit measurement in Chapter Twenty-Six in [2].

4.2 Domains, Performance Groups, and Periods

TYPE72 observations are created for each period of each performance group. A performance group is simply a number that is assigned to a task by the installation for resource reporting and labeling. A task keeps the same performance group for its entire execution duration (except that batch steps can change performance groups by specifying a different value of PERFORM= on an EXEC statement). The SYS1.PARMLIB IEAICSnn member (which ensures that work is controlled) defines the performance group for each task in a hierarchy that you create.

Performance groups are assigned to tasks in ICS first by subsystem:

```
STC
JES2/JES3          PGN=nn
TSO
```

unless you specify performance group by job name or job class:

```
TRXNAME=MYJOB      PGN=mm
TRXCLASS=A         PGN=oo
```

or unless you specify performance group by userid:

```
USERID=BERNIE      PGN=pp
```

Performance groups can be subdivided into periods so that the resources consumed by transactions or steps can be controlled. You may wish to reward the interactive users by giving them high levels of service, but you may also wish to punish the batch user who executes his stage-one SYSGEN under TSO. The periods are defined by the DUR parameter, which sets the number of service units to be permitted in each period. When a task exceeds the DUR value, the SRM detects that event and transfers the task to the next period:

Period One	Period Two	Period Three
DUR=300	DUR=1000	
PRTY=HI	PRTY=MED	PRTY=LOW
DMN=5	DMN=4	DMN=6

Figure 3. Periods within a Performance Group

The performance group period defines the domain in which the task is to execute, and the domain definitions determine the priority and service level that the task receives.

Domains are numbered collections of tasks that are to be treated equally with regard to service-unit consumption. Note that tasks commonly change their domain during a transaction's execution.

Because the SRM chooses domains for service delivery, a large number of domains is unnecessary, unwise, and can increase the MVS overhead. Performance groups have no overhead; they are simply buckets in which the service units and transaction counts are stored when a transaction ends. Therefore, it is common, and in fact wise, to have a large number of performance groups. It is strongly suggested that you place each long-running address space (that is, each CICS, each IMS control region, each IMS message region, the RMF, and so forth) in a separate control performance group. This permits TYPE72 data to be invaluable in determining workload growth over time as well as measuring the percentage of the peak-hour resources that each workload consumes. Although separate performance groups for each long-running task are desired, all tasks that are alike (for example, IMS message regions) can be mapped to the same domain so that the SRM will treat them equally.

The ratio of RESIDTM to DURATM gives the average number of address spaces in this performance-group period (that is, in this domain) that were resident in real memory. This is commonly referred to as the multiprogramming level (MPL) for the performance-group period. For example, the ratio can be calculated for all periods of TSO performance groups to determine the average number of TSO users in real memory.

The difference between ACTIVETM and RESIDTM is the swap-in delay time. If this difference is divided by TRANS, the average swap delay (in seconds) for each transaction is known.

5. TYPE74 DEVICE MEASUREMENT

5.1 RMF Device Activity

In addition to the following discussion of device measurement at the device level, see the TYPE78IO, TYPE78CF, and TYPE78CU sections in [2].

TYPE74 is the primary source of information for managing and measuring the DASD I/O environment in MVS/XA. Although TYPE74 data can also be used for some measurements of tape I/O activity, the techniques described in Chapter Fourteen are generally more appropriate for tape analysis.

MVS/XA captures data that are recorded in hardware monitors that are built into the channels. The data measured at the device level provide complete and

detailed data on the I/O activity. The actual data that are recorded in type 74 records consist of a number of duration measurements. For example, the duration during which data were actually being transferred between the CPU and the device is measured by DEVCONTM (the number of seconds of device connect time during the RMF interval).

In addition to this absolute duration measure, you can examine each measure from two other useful perspectives. If you divide the measured duration by the RMF interval duration, you get the percentage of time when data transfer was occurring (PCTDVCON). If you divide the measured duration by the number of I/O operations, you get the average milliseconds of connect time (AVGCONMS) for each SIO (actually, for each start subchannel (SSCH) instruction). Because all three perspectives are useful, MXG creates a variable for each perspective in TYPE74.

The power of TYPE74 analysis lies in the completeness of the measures of both the utilization and the delays at the device level. The next figure identifies the major durations (and their alternate perspective variables) that are created in TYPE74.

```
      AVGACTMS  - Average Active Milliseconds per SSCH
      DEVACTTM  - Total seconds active time
      PCTDVACT  - Percent of interval when active

|-------------------------------------------------------|
                          Active

        AVGPNDMS              AVGDISMS      AVGCONMS
        DEVPNDTM              DEVDISTM      DEVCONTM
        PCTDVPND              PCTDVDIS      PCTDVCON

|-----------------------|-----------|-------------|
        Pending           Disconnected  Connected

three components of       RECONNECT (RPS)
pending time measured.

  Typically 1-5 ms       Typically 9-27 ms   Min. value
   per SSCH               per SSCH            1.3 ms  4K
                                             14.9 ms 47K
```

Figure 4. MVS/XA Device Measurement Components

In addition to the actual hardware measurements of disconnected and connected durations, RMF samples UCB bits to calculate the additional percentage of time when the device was reserved but was not involved in an I/O operation (PCTDELAY). The sum of PCTDVDIS, PCTDVCON, and PCTDELAY is PCTDVUSE (the percentage of time that the device was in use). PCTDVUSE describes how long the device was "tied-up" and could not be used to service a request from any other system.

The MVS/370 measure of device utilization, DEVBUSY, was replaced by PCTDVUSE:

```
                          PCTDVUSE
  |-----------------------------------------------|
                    Device Utilized

       AVGDISMS       AVGCONMS
       DEVDISTM       DEVCONTM
       PCTDVDIS       PCTDVCON       PCTDELAY

  |---------------|--------------|-----------------|
    Disconnected     Connected      Reserved with
                                      no I/O
```

Figure 5. MVS/XA Device Utilization Components

Yet another measure is sampled by RMF: the average number of I/Os that were enqueued in IOS (that is, delayed in the input/output supervisor because an I/O was already outstanding to this device from this system). Knowing the average number of I/Os that were queued permits the calculation of the average milliseconds of IOS queue time for each SIO (AVGIOQMS). With this additional value, the average response time in milliseconds for each SIO can be determined:

```
                          AVGRSPMS
|-------------------------------------------------------|
        Average Response Milliseconds per SIO

  AVGIOSMS      AVGPNDMS        AVGDISMS      AVGCONMS
                DEVPNDTM        DEVDISTM      DEVCONTM
                PCTDVPND        PCTDVDIS      PCTDVCON

|----------|--------------|---------------|-------------|
 IOS Queue     Pending        Disconnected    Connected
```

Figure 6. Average DASD Response Components

5.2 RMF Device Report

The RMF direct access device activity report column headings are shown below in lowercase; the MXG variable directly corresponding to each column is indicated in uppercase. Using PROC PRINT SPLIT='*'; with a VARIABLES statement naming these variables would create the report.

Table 7. RMF Device Report Variables

PCTRESVD	AVDSOPEN	PCTALOC	MOUNT

6. TYPE78.. I/O FOR 3090

Seven different TYPE78.. data sets are created from the three subtypes of the type 78 RMF records. Subtype 2 contains virtual storage measures that create TYPE78PA, TYPE78SP, and TYPE78VS data sets. The subtypes 1 and 3 contain I/O measures that are structurally different depending on the processor on which the data are created:

Table 8. Sources of I/O Measurement

308x and 4381		309x	
MXG Data Set	Subtype	MXG Data Set	Subtype

TYPE74	LCU DEVNR VOLSER IORATE PCTDVPND PCTDVDIS PCTDVCON AVGRSPMS

6.1 RMF I/O Queueing Activity

The RMF device activity report has already been described in the preceding TYPE74 section in this supplement. The RMF I/O queueing activity report described below combines information from the TYPE78IO, TYPE78CU, and TYPE78CF data sets, which are described in more detail in their own sections in [2]. The following report is described as it exists for RMF 3.4.1 on a 309x processor:

----------from TYPE78IO----------

iop	activity rate	avg q lngth
IOPIQID	IOPACTRT	AVGIOPQL

-----from TYPE78CU-----

lcu	contention rate	delay q lngth
LCUID	CUHACTRT	AVGCUHQL

----------from TYPE78CF----------

ch path busy	control units 1	2	3	4	chan path	chpid taken	% cu busy
Note 1	CU1	CU2	CU3	CU4	CHPID	CHPIDTKN	PCTCUBSY

Note 1:
For each TYPE78CF observation, the PCTPTHBY variable exists, and it is identical with the TYPE73 PCHANBY variable for that CHPID. The RMF queueing activity report takes the product of PCTPTHBY for each CHPID within each LCUID as the estimated probability that all channel paths are busy within this LCUID.

Figure 7. RMF I/O Queueing Activity

There is one observation for each LCUID in TYPE78CU. In TYPE78CF, there is one observation for each CHPID within each LCUID, with up to four CUs connected to that CHPID. Thus, there may be several lines from TYPE78CF for each LCUID from TYPE78CU.

6.2 TYPE78CF MVS/XA Device Configuration

There is one observation in TYPE78CF for each combination of a CHPID (Channel Path ID) within each LCUID (Logical Control Unit ID).

TYPE78CF is built from type 78 subtype 1 records if the processor is a 308x or 4381, or from the type 78 subtype 3 record for 309x processors.

Prior to 309x processors, the TYPE78CF data set was only a static description of the physical connectivity of physical control units, their channel paths, and their logical control units. The 309x machines have added four important utilization statistics: the percentage that all channel paths were busy, the rate at which I/Os were taken on this CHPID for this LCUID, the percentage that all paths were busy to this LCUID, and the percentage that physical control units were busy on this CHPID LCUID combination. While TYPE74 still remains the primary source of I/O delay measurement, once a candidate problem device has been identified, TYPE78CF can provide amplification of potential path problems.

6.3 TYPE78CU MVS/XA 309x Control Unit Header Queue

There is one observation in TYPE78CU for each LCUID (Logical Control Unit ID). TYPE78CU is built from the type 78 subtype 3 record for 309x processors only. It describes the activity and queueing for the control unit header queue.

6.4 TYPE78IO MVS/XA 309x Input-Output Processor Init Que

There is one observation in TYPE78IO for each IOP. TYPE78IO is built from the type 78 subtype 3 record for 309x processors only. It describes the activity and queueing for the IOP initiative queue.

7. TYPE78VS MVS/XA Virtual Storage Statistics

Some virtual storage measures in TYPE78VS are contained in sets of ten variables whose suffix (0-9) identifies the content of the variable. Some virtual storage measures have a suffix of 0-4 because that area exists only below the 16MB line. It is the area below 16MB that is most critical because many system functions can exist only below the 16MB line.

Table 9. Suffix of Virtual Storage Measures

--------Below 16MB--------					--------Above 16MB---------				
min value	time of min	max value	time of max	avg value	min value	time of min	max value	time of max	avg value
0	1	2	3	4	5	6	7	8	9

The time stamps (suffixes 1, 3, 6, and 8) are correct in the type 78 record (and, thus, in MXG), but a close examination of the RMF report will show time stamps that are earlier than the beginning of the RMF interval (even with RMF 3.4.1). The error results from truncation in an internal calculation in the IBM RMF report program. The RMF printed value is typically 1 to 4 seconds earlier than the correct value. This error has been reported to IBM.

The RMF virtual storage activity report from TYPE78VS data is shown below. Report columns are in lowercase, and MXG names are in uppercase.

Figure 8. RMF Virtual Storage Report

8. MVS 2.2 ANNOUNCEMENT

MVS/XA 2.2.0 (JES2) and 2.2.1 (JES3) and associated RMF 3.5 have been announced for 3rd quarter 1987 availability. This discussion is based only on the IBM Announcement of those products.

8.1 NEW SMF RECORDS

36	ICF (Integrated Catalog Facility) Export/Import
41	DIV (Data In Virtual) Access
90.17	Subtype for Set PFK

8.2 NEW SMF DATA

The type 30 record will contain the number of Data In Virtual (DIV) rereads in the step and job termination records and in the interval records.

The type 72 performance group period data will contain (finally!) paging statistics for each period of each performance group.

If the type 4 and 34 SMF records are not already dead, MVS 2.2 is their final poison. The Task I/O Table (TIOT) is expanded from 32KB to 64KB in MVS 2.2, which allows for 3273 DDs (compared with only 1635 DDs). The type 4 and 34 SMF records do not support more than 1635 DDs, but instead contain a "not here" bit, indicating that the step had more than 1635 DDs and that I/O counts for the excess will only be found in the type 30 records.

The Selectable Unit Installed bit string in the type 70 record does not exist in MVS 2.2; it had not been updated since MVS/370.

8.3 SMF RECORD SUBTYPE SELECTIVITY

A bit in record types 30, 32, and 70-79 allow selectivity of record subtypes. The selectitity can be specified in SYS1.PARMLIB (TYPE,SUBTYPE) to selectively create records, or it can be specified in parameters to the IFASMFDP program for dumping selectivity by subtype.

8.4 INCOMPATIBLE CHANGES

IBM has stated that programs that do not use the relocatable format information in the type 30, 72, and 79 will be affected by incompatible changes to those records.

The documentation of these new changes in SMF data were released in April, 1987, in GC28-1411 MVS 2.2 Conversion Notebook Volume 2. IBM should be congratulated for the early release of the documentation of these changes which affect the format of existing data records.

8.5 MVS 2.2 PERFORMANCE ITEMS

The following items in the announcement should be noted.

Many control blocks were moved above 16MB to ease virtual storage constraints. This will likely affect all system monitors; check with your monitor vendor for a new version/release of their product.

Global Resource Sharing (GRS) will have a larger RSA (up to 32K, or 8 pages), the QWB will be variable length, and the SMPL is compressed from 96 to 28 bytes. This leads to more QWBs per page and to more QWBs per RSA, which should reduce delays in the GRS processing time.

The DUAL option for the JES2 checkpoint data set should reduce I/O on the SPOOL.

Multiple JES2 output PCEs can be defined, leading to improved print throughput.

All SVCs are now defined in IEASVCxx and the SVC table is now page protected. This requires all SVC users to use SVCUPDTE which will also affect system monitor vendors.

Expiration dates through year 2155 are now supported, with 99365 and 99366 protected from ever expiring. Why through 2155 you ask? Because there are 255 years from 1900 to 2155 and a one byte counter for the years since 1900 are used! SAS-provided formats and functions like SMFSTAMP8. and DATEJUL() will undoubtedly be revised to handle the new format. At present, however, only the EXPDT in the type 14 and 15 records, a packed decimal date without associated time, can be in the next millenium.

Now that extended storage has virtually eliminated the need for page or swap data sets, MVS 2.2 will support up to 256 separate swap or page data sets.

Up to 9999 report performance groups can be defined, with the limit of 999 control performance groups unchanged.

The RMF Monitor II value of CPU=101, which indicates that the CPU is actually 100% busy and in addition there was at least one ready task which was not dispatched during the last five elapsed seconds, will now count the actual number of undispatched ready tasks, up to a maximum of 28. You might even see CPU=128 in the future.

The Logrec buffer has been increased from 4KB to 16KB.

Partioned Data Sets and QSAM disk files can be concatenated in any order. It is no longer necessary to specify the largest blocksize first. Apparently, IBM must have finally found its own documentation of the SILI bit fondly remembered by OS/360 system programmers.

9. ONE MIPS AND TWO MEGS - SOME FOOD FOR THOUGHT

In the late 1970's, Walt Doherty, of IBM's T.J. Watson Research Center, concluded from studies of highly interactive development CMS users that each such user truly required only 1-2 MIPS and 2-4 MEGs, "on demand".

Studies of TSO user data suggests that no more than 10% of the logged on TSO users are actually active, that is, in and ready, or "on demand."

With 500 logged on TSO users on a 3090-400 with 128MB memory, only 50 users would be expected to be in and ready on this 50 MIPS machine, and each "on demand" user would have 2 MB of memory even if we allowed the operating system to own 28MB. Thus this machine would provide one MIPS and two MEGS to each "on demand" user.

Conversations with many sites with this hardware and workload seem to subjectively confirm that 1 MIPS and 2 MEGS provides unconstrained TSO response.

Another 3090-400 with 50MIPS and 128MB supported eight CICS applications which showed a total peak maximum active tasks (equivalent to the TSO in and ready, or "on demand") of 48. No response delays were noted, and the eight CICS applications recorded not one single page fault for the entire week. One MIPS and two MEGS seems also to meet CICS needs.

The advent of extended storage has finally provided our programs with enough real memory to execute, unconstrained by storage limitations. This in turn has reduced some of the operating system overhead which was consumed in serving the paging, but more importantly, the massive reduction in page service time (70 microseconds for extended memory, 30,000 micro seconds from disk) has eliminated significant delay to the user response. We see reduced resources for better response.

I believe that when the user notices the response time, it is already too long.

What will happen when you have the hardware to provide one MIPS and two MEGS for each "on demand" user? Your capacity planning headaches will go away, and computer growth will be tied directly to user population. The user population is constrained by new employment, which itself is constrained by profit. Rare is the company whose profit increases more than 10% per year.

Once you have provided unconstrained response to your users, only adding more users will require more hardware. Since you have already computerized almost all of the repetitive business functions, new development may add function and ease of use, but will not likely increase the number of concurrent business users of those repetitive business functions.

Ah, but what about those fourth generation languages that eat resources? Won't they fill my CPU and memory? There are certainly some industries which can take advantage of computer power in relational data bases to further the business purpose. I suspect, however, these companies are few and far between. Furthermore, how many employees will need to execute these long running complex transactions, and how many times a month will these "analyses" be required? If they produce complex results, is it not likely that many hours will be

required by humans to analyze the results, to establish marketing plans based on the results, etc.?

I am not suggesting that all computer growth is coming to an end. There are many well known problems which are just being feasibly solved which need much more power to be accurately solved. (Predicting weather has been described as needing 9 dimensions, while current computers can only support 3 dimensions, and then only for a 5-day prediction). But for the run-of-the-mill business data processing (invoicing, accounts receivable, returns, credits, payroll, etc., etc.), which has been the main driving factor of computer growth since the first 650 was shipped, I believe the compound growth rates we have seen are a thing of the past. If you install the right amount of hardware and software to do the job, then you won't need a job position to figure out how much hardware and software you need.

EXPERT SYSTEMS AND MVS PERFORMANCE MANAGEMENT

J. van Kinsbergen
Boole and Babbage, Inc.

ABSTRACT

This paper will focus on the author's definition of expert systems, and its application to and issues with the problems of MVS performance management. It will establish what is and what is not expert system technology and then the time dimension of performance management. Finally, interfacing expert systems to the MVS environment will be discussed.

THE PROMISE OF EXPERT SYSTEMS:

PRODUCTS DEVELOPED WITH EXPERT SYSTEM TECHNOLOGY WILL PROVIDE LABOR-SAVING DEVICES THAT WILL ALLOW SYSTEMS PROGRAMMING EXPERTS TO FOCUS ON REAL ISSUES AND OPPORTUNITIES WORTHY OF THEIR EXPERTISE. EXPERT SYSTEMS TECHNOLOGY WILL NOT REPLACE EXPERTS, BUT WILL ENHANCE THEIR ABILITY TO FOCUS, AND THE NOVICE'S ABILITY TO PERFORM AS AN EXPERT.

1. WHAT IS EXPERT SYSTEM TECHNOLOGY?

JUST BECAUSE A SOFTWARE IMPLEMENTATION DOES EXPERT THINGS DOES NOT MAKE IT AN EXPERT SYSTEM.

It is instructive to discuss first what expert system technology is not. Expert system technology does not merely:

1. Do expert things
2. Mimic human reasoning
3. Capture knowledge
4. Have rules

While expert system tehcnology applications in many cases will demonstrate some or all of these attributes, the same can be said for many other software systems. Just merely doing the above does not constitute an expert system; as we well know, there have been many implementations over the last thirty years of software packages that could say they accomplished the above items.

EXPERT SYSTEM TECHNOLOGY IS THE FIFTH GENERATION IN THE EVOLUTION OF PROGRAMMING LANGUAGES (I.E., COMPILERS)

In my opinion expert system technology is the current generation of the evolution of application development languages over the last thirty-five years. The generations are as follows:

1. First generation, machine languages
2. Second generation, assembler languages
3. Third generation, procedura languages, e.g., PL/1, COBOL
4. Fourth generation, form-driven "programmerless" languages
5. Fifth generation, expert system languages

Another part of the confusion comes from the terminology that has been created. There has been extraordinary work done over the last several years in the development of expert system technology; however, I believe that it has been allowed into the commercial marketplace without proper "scrubbing" by the general marketing and business community. We therefore have new terms to define old activities. At this point I would like to define these equivalences.

MUCH OF THE TERMINOLOGY ASSOCIATED WITH EXPERT SYSTEMS (INCLUDING THEIR VERY NAME) CAN BE CONSIDERED TO BE REDEFINITIONS OF HISTORICAL TERMINOLOGY. THE MOST IMPORTANT ADVANCEMENT IN EXPERT TECHNOLOGY THEN IS THE INFERENCE ENGINE OR APPLICATION CONTROL PROGRAM.

Fifth Generation Language

Expert System Technology
Knowledge Base
Inference Engine
Rules
Knowledge Engineer

Third Generation Language

Compiler with Run Time Option
Source Code
Run Time Option
Application Logic
Application Analyst

For example, the knowledge engineer is the person who sits down with the user expert and lays out what is required for the implementation of the application. With new expert systems technology the applications are more varied and complex; nevertheless, the knowledge engineer can be considered to be the application analyst of the future.

The knowledge base consists of rules implemented by the "knowledge engineer" in a form consistent with what we have historically called source code.

The most significant new item is the inference engine. The inference engine can be looked at as an extension of the operating system control program. As you are well aware, operating systems provide two major functions:

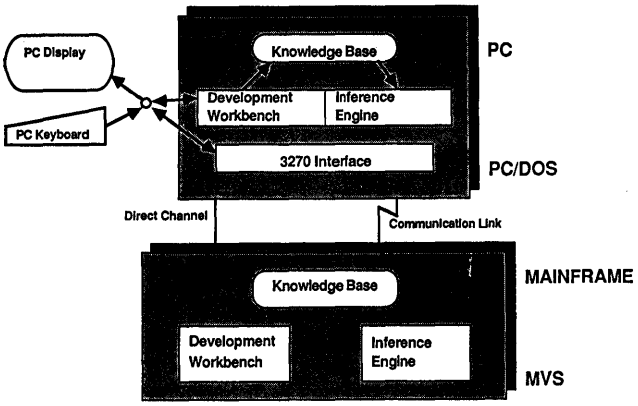
1. Control the interaction of work units in the system
2. Provide common services

The inference engine does exactly this in concert with the compiled source code created by the knowledge engineer. The inference engine is an application control program that runs in the application address space; controls the flow of work (rules), and provides common services to tasks within this application. In my opinion it is an extraordinary development in the evolution of programming languages and frees the programmer analyst from writing code that controls the flow of work within the application. That is, he does not have to write code that decides when to set or test a flag, or read input, etc. I am sure that you will agree with me that a major portion of application development consists of creating code that just gets the application from one piece of logic to another. The inference engine component of an expert system provides this capability. The robustness of the expert system can be measured by the capabilities of the inference engine.

The knowledge base itself consists of separate knowledge objects that are managed by the inference engine. These knowledge objects can consist of rules, variables, messages, reports, external files and/or external processes. The existence of the inference engine, and the technology that supports it, allows the developer to treat these knowledge objects as separate items in the development process. "If - then - else" rules can be entered into the system in an independent and "asynchronous" manner. The inference engine will tie these rules to existing or future variables as well as input and output. This inferencing process, both on the development side and the execution side, represents the most significant new technology provided by expert system language capability.

Figures one and two represent an example of an expert system consisting of two parts: a development system and the execution system, both of which execute in both the MVS mainframe and PC/DOS environments. This allows the developer to take advantage of the significant productivity gains in the PC environment but create code that is targeted for the mainframe environment. There is complete portability between the two, and thus significant productivity gains by taking advantage of the best of both worlds.

FIG 1. PC/MAINFRAME ARCHITECTURE



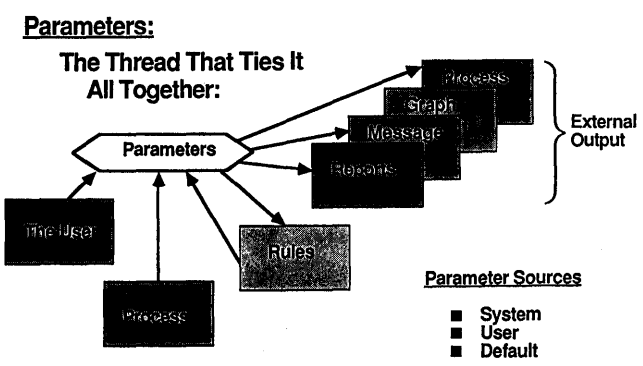
The development system has several "object editors" that allow creation and editing of the following objects:

1. States. This is the major modular unit of an application, equivalant of a subroutine.

2. Types. This unit allows the developer to create his own record formats or to use the types that come with the system. The built-in types include real and integer numbers as well as strings, lists, sets, and booleans.

3. Rules. Are of the production rule form: if - then - else. Major capabilities exist that allow iterative rules as well as the equivalent of case statements allowing multiple logic to be included in a single rule.

FIG 2. TECHNOLOGY EXAMPLE



4. Input and output and logic modules. Managed through the state, report, message, graph, and process objects. Each of these objects has input rules associated with them which control when the inference engine will fire off the function. And finally the process object allows access to external data and/or "foreign code". Again these process objects can be invoked based on input selection, and rules as described above.

The inference engine provides both forward chaining and backward chaining capabilities. Most effective in my opinion is the backward chaining process. In this case we establish a goal to be resolved, and the inference engine will backward chain through the logic to support it. An example would be the creation of a report with specific output variables imbedded. These variables are defined to the system in the form of parameters. The inference engine will start with these parameters and search its rule and process base in order to determine how the parameters are satisfied. In some cases, access to the keyboard will occur. As the inference engine determines a rule that can satisfy a parameter, it will in most cases require other parameters in order to fire the rule. This will require chaining further back to other rules, processes, or the keyboard again. This process continues until the very lowest level parameters are determined, which then cause the rules, etc., to be escalated back until the parameters in the goal (report) have been satisfied. This allows tremendous nested logic to be created in a manner that is completely beyond the mental capacity of a procedural approach. Because the inference engine controls the flow of work, it also can provide significant other run time facilities to support the application. This includes explain facilities as well as run time debugging options that enhance the understanding and maintainability of the application.

This technology example provides the following attractive features:

1. Significantly increased development productivity due to the object oriented approach to development as well as the basic workbench capabilities.

2. Because of the independence of the rules, the limitations associated with the nested approach to logic statements disappear. Logic can be pursued that heretofore was impossible.

2. MVS INTERFACE ISSUES

Expert systems operate best when they are digesting "facts". They are not designed just to deal with presentation and formatting of numerical data as are previous generations of development languages. Their focus is to take facts; draw conclusions, and allow the creation of an analytical set of logic. Procedural languages on the other hand are much better for numerical processing. However, in any production data processing environment numerical data obviously is a key component, in particular, in the performance management area. We obviously have been generating extraordinary amounts of data and information for years and not too many facts and conclusions. The interface of expert systems to the MVS environment for the inplementation of performance management products will be eased if the data that is presented to the expert system is presented in the form of facts. An example would be, "device 526 has an RPS problem; does not have a seek problem; does not transmit too much data." This is a series of facts that have been deduced by analyzing large amounts of performance data in a procedural manner. The inference engine will do a very fine job of taking the facts for the entire configuration, such as above, comparing them, and deciding what the facts mean. The example fact above taken on its own is interesting, but probably not sufficient. The analysis of all of the facts in a global context is an area in which the inference engine technology should be very effective. There are other areas of concern, but this is the most significant issue associated with expert system and performance management.

THE MOST SIGNIFICANT ISSUE ASSOCIATED WITH THE INTERFACE OF EXPERT SYSTEMS TO MVS PERFORMANCE MANAGEMENT PRODUCTS IS THE PROPER PREPARATION OF MEASUREMENT DATA IN ORDER TO OPTIMIZE THE EXECUTION OF THE EXPERT SYSTEM.

2a. THE TIME SPECTRUM OF PERFORMANCE MANAGEMENT

Performance management in its entirety consists of the support of
three major areas:

1. REAL TIME
2. CURRENT TIME
3. FUTURE TIME

The REAL TIME environment is the one on the machine room floor. It is analogous to the gauges and controls in your automobile.

The CURRENT TIME environment consists of the tuning of the configuration as it exists on the floor. It does not include the planning for new hardware; it merely involves the optimization of the hardware and software as it exists today. It is analogous to the tuning of your automobile including adding new tires or sparkplugs, and the optimization of the automobile by the garage mechanic. This is more of a batch process and tends to operate against historical, although reasonably current information.

And finally, FUTURE TIME consists of the planning for future equipment acquisitions or changes. This is analogous to planning for your next automobile. How big should it be, what new features are available, what new models are available?

The CURRENT and FUTURE TIME environments can include significant batch reduction of data and creation of reports in a form either on paper or browsed online in some interpretive manner. Also included, to test hypothetical solutions, should be an analytic model to support the "what if" environment. Notice the model is included in the CURRENT TIME situation, since the testing of "what if" resolution to CURRENT TIME tuning issues is important as well. As for FUTURE TIME issues, heretofore we have applied the model to the FUTURE TIME situation, but more and more we are seeing modeling capabilities surface to address CURRENT TIME situations as well.

The application of expert systems to these three environments is certainly feasible. The key, as I discussed previously, is the preparation of data in a form that is acceptable to the expert system. For that reason the most promising initial application of this technology is in the CURRENT TIME and FUTURE TIME environments. Although REAL TIME applications can occur, the time sensitive nature of responding in a real time manner dictates that major improvements in performance monitor technology be created. This is not as big an issue in the CURRENT or FUTURE TIME as batch reduction is an acceptable component of the process.

2b. PERFORMANCE MANAGEMENT EXPERT SYSTEM OPPORTUNITIES

PRODUCTS DEVELOPED WITH EXPERT SYSTEM TECHNOLOGY WILL PROVIDE LABOR-SAVING DEVICES THAT WILL ALLOW SYSTEMS PROGRAMMING EXPERTS TO FOCUS ON REAL ISSUES AND OPPORTUNITIES WORTHY OF THEIR EXPERTISE. EXPERT SYSTEMS TECHNOLOGY WILL NOT REPLACE EXPERTS, BUT WILL ENHANCE THEIR ABILITY TO FOCUS, AND THE NOVICE'S ABILITY TO PERFORM AS AN EXPERT.

In all of the three environments of the time spectrum (REAL TIME, CURRENT TIME, FUTURE TIME), the analysis of the configuration in order to detect contention and pinpoint bottlenecks is the most promising application of this new technology. Heretofore, performance products have produced a lot of information, but require a systems analyst to determine bottlenecks and pinpoint the problems. We believe that expert system technology can be applied to this process. Specific opportunities in each area also include:

1. FUTURE TIME - optimal design and in particular test driving the model in an iterative manner.
2. CURRENT TIME - analyze SRM data and suggest the setup of IPS parameters.
3. REAL TIME - intelligent help facilities for the operator. That is, help facilities that assist in the analysis of detected problems as directed by the operator himself.

It is important to understand that expert system technology will not replace system programmer expertise. What it will do is allow the system to capture some of the knowledge of these experts so that novices or operations personnel can begin to address the operational management of the performance of the data center. This requires that performance data be reduced and put in a form that is understandable to someone who is less highly trained than your average performance analyst. In addition, we see this technology as providing the ability to produce products that will become labor-saving devices for the expert systems programmer. In other words, he will be free to focus on problems that truly require his depth of experience and knowledge rather than the more mundane kinds of things that today cannot be handled by anybody else. For example, the analysis of hundreds of disk drives in order to determine their performance characteristics is something that requires such expertise, but clearly is not performed on a regular basis. The regular execution of an expert system reading DASD performance data can produce focused analysis and advice that the less trained systems personnel can either follow or discuss with the performance expert for his data center.

In the long run, I am confident that expert systems technology can begin to apply process control techniques to the computer center environment although that is not something that will happen in the near future.

3. CONCLUSION

In conclusion then, I believe that expert systems technology is the fifth generation of the evolution of development languages. As such, it provides significant capability for the implementation of new performance management capabilities as well as a tool for addressing the programmer productivity and application backlog issue. It has application across the entire time spectrum of performance management issues, but because of the nature of the input data required, the initial implementations will surface in the CURRENT TIME and FUTURE TIME arenas with REAL TIME implementations requiring improved performance data sources. And finally, that expert systems will not displace experts but will focus them on real issues, and upgrade the level of capability of the novice to perform at an expert level.

EXPANDED STORAGE USAGE AND TUNING

Carolyn Hanna
McDonnell Douglas Aerospace Information Services Company

ABSTRACT

A study was done on the use of expanded storage on a 3090-400. The basis of the study was a problem of high MVS overhead which appeared to result from high use of expanded storage and auxiliary storage. The application in the study in TSO/CADCAM. This paper will present an overview of real, expanded, and auxiliary storage. The tuning parameters for expanded storage and methods for monitoring and measuring the use of expanded storage will be described. The results of tuning and parameter adjustment in an attempt to efficiently use storage and reduce the MVS overhead on the 3090-400 are reported.

INTRODUCTION

The introduction of the 3090 family of processors brought in a new feature, expanded storage. Expanded storage provided the necessary relief for paging and swapping, system performance improved initially. As the load on the system grew, so did the use of expanded storage and migration, and so did the MVS overhead. Overhead is unaccounted CPU time. Migration is the movement of a page from expanded storage to auxiliary storage. The page is moved from expanded storage to central storage and then out to auxiliary storage.

This author began to experiment with the expanded storage parameters in IEAOPTxx in an attempt to tune a heavily loaded system. The tuning environment is described in Figure A. The original tuning goal was to direct more work, mainly batch, to auxiliary storage as a storage crisis was in full swing. By moving pages directly to auxiliary storage the demand on expanded storage and migration would be reduced. This would then reduce any associated MVS overhead. The high use of expanded storage was believed to be causing a high amount of MVS overhead (25% or greater).

After a sharp learning curve which will be shared with the reader, several parameter settings were tested. The results of these adjustments, and an overview of expanded storage are presented in the following sections of this paper.

OVERVIEW

Expanded Storage is a hardware feature available on the 3090 family of processors. It is part of the hierarchy of storage which includes central storage, expanded storage, and auxiliary storage.[4] Refer to Figure B. Expanded storage was introduced as an alternative to DASD paging. It is managed by the Real storage Manager (RSM) and the System Resource Manager (SRM).

RSM plays a dual role in the use of expanded storage. One role is to determine which pages go to expanded storage and which go to auxiliary storage. The second role is to manage the migration or removal of pages from expanded storage to auxiliary storage. A page that is migrated from expanded storage to auxiliary storage must first be sent back into central storage before going to auxiliary storage. Page movements involving expanded storage are synchronous and performed a page at a time for both page and swap activities.[9] VIO activity is to auxiliary storage. The following terms will be referenced in the remainder of this paper:

- The Unreferenced Interval Count (UIC) is an indicator of the contention for real storage. The average system-high UIC is a measure of how long a page has remained unreferenced in real storage. The value is in seconds. When the UIC is low, contention for storage is high.[4]

- The Migration Age (MA) is an indicator of the age of a frame in expanded storage. This value is in seconds. It is not an actual count like the UIC, instead it is a calculation done by the SRM based on the length of time required to cycle through the expanded storage table. More accurately, it is an indicator of the demand on expanded storage.

- The Criteria Age (CA) is an estimate of the time a page will remain in central or expanded storage. The Criteria Age is specified in the OPT, and can be set for several types of pages which will be addressed later. This value is used in the selection formula by RSM when deciding to send a page to expanded storage or to auxiliary storage. The larger the criteria age value, the more likely the page is to go to auxiliary storage. The criteria age can be set in the range 0 - 32767. The value is in seconds. The criteria age is a set value, determination of the setting is made by monitoring the migration age and the UIC for the system.

Throughout this paper the terms real, expanded, and auxiliary will be used to refer to real storage, expanded storage, and auxiliary storage respectively.

STORAGE HIERARCHY

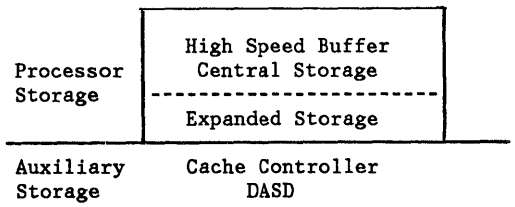

Figure B

OPT KEYWORDS

There are 8 keywords (22 specifications) in the OPT for which the Criteria Age (CA) can be set. Keep in mind the higher the criteria age the more likely a page will be sent to auxiliary storage based on the decision formula.

The CA default values used in the formula are low and always default to expanded storage. These values are displayed in Figure C. From this author's observation of a heavily loaded system, where the page movement rate from central to expanded storage was over 1800 pages a second, the migration age never dropped below 350 seconds. The movement of pages to expanded storage and the migration age are reported in OMEGAMON and RMF. Since the highest default value for criteria age was 100, pages always went to expanded storage.* In such a case the criteria age must be set at 350 or larger to be effective. These parameters must be continually adjusted based on the system load and the migration age being experienced. The low, high, and average migration age for an RMF interval are reported in the RMF Paging Activity Report shown in Figure D.

The OPT keywords are as follows:

ESCTPOC(n) -changed page-out pages
ESCTPOU(n) -unchanged page-out pages
ESCTSTC(n) -changed stolen pages
ESCTSTU(n) -unchanged stolen pages

For the above parameters the decision formula is: MA > CA.
For swap pages the keywords are:
ESCTSWTC(n) -changed swap-out pages
ESCTSWTU(n) -unchanged swap-out pages
ESCTSWWS(n) -working set pages ready for swap-out

For the above parameters the decision formula is: UIC + MA > CA.
An exception to this is ESCTSWWS(2), terminal wait pages are sent to expanded storage when: (UIC + MA) - Think Time > CA.

For the above seven keywords (n) takes on the following meaning:

0 - nonswappable/common/privileged users
1 - all others not 0 or 2
2 - Terminal wait swap users/or TSO users

The eighth keyword is for Virtual Fetch:
ESCTVF - virtual fetch pages
The decision formula for virtual fetch pages is: MA > CA.

*The average UIC=20, Think Time=10 (OMEGAMON)

For clarification, the specification of ESCTPOC(2)=400 in the OPT would set the criteria age at 400 for all changed page-out pages for TSO users. These parameters are outlined in the Initialization and Tuning Guide(5). To simplify the tuning effort, the OPT can be changed dynamically by use of the set command: SET OPT=xx. Setting the OPT during an RMF interval does not cause the interval to reset.

THE DECISION

An indicator of the contention for storage is determined (left side of the inequalities) and compared to the CA. When the inequality is true the page goes to expanded storage, when the two sides are equal or the right side (CA) is greater then the page goes to auxiliary storage.

MONITORING EXPANDED STORAGE

The three tools used to monitor expanded storage usage were OMEGAMON, DEXAN and RMF. These are very similar since OMEGAMON and DEXAN use RMF data.

OMEGAMON allows real time visibility into a dynamic system. The migration age value, migration rate, and various other expanded storage values can be viewed through a series of commands. For monitoring the use of the OPT values and expanded storage this author set up the screen space presented in Figure E. The values displayed are for a 3090-400 before any OPT settings were implemented. This screen space will be revisited in the section on tuning results. The most important point here is that the analyst realize what is being reported. For example the OMEGAMON system paging displays do not include paging to expanded storage. The expanded storage displays must be viewed separately. Therefore, in Figure E, the SPAL does not include paging to expanded storage. The page fault rate and page delay time (RPAG,RPDL) are only reporting auxiliary storage values.

When the CA values are in effect, viewing the MPAGxx and MPGIxx displays will reveal the effects on the paging packs. The MPAGxx reports only auxiliary storage paging. The SRCT display is valuable, specifically SRCT.R, to see the rate at which pages are sent to auxiliary, expanded, or migrated from expanded for various swap reasons.[3] The 'ESMG' command in Figure E displays the current OPT settings. When a setting is invoked, an asterisk is displayed next to it. When the MA is below the set value, it will not be invoked until a decision is made involving the specified type of page. For example, you may set CA for batch, if there is no batch on the system it is not invoked. If you have OMEGAMON V685 the ESMG display may be incorrect (BATCH and TSO are reversed) and a zap is available to fix the problem. It is important to check this before you set CA values since it could be confusing as to which values are actually in effect. The impact of sending all swap for batch to auxiliary storage is much different than sending all swap for TSO. For individual users, the ESFC - frame count value will display the number of expanded storage frames a user has. A swap to expanded storage is not included in the swap count however.
DEXAN reports the wait reasons and time for a performance group or period. EPILOG gives this visibility also. The DEXAN interval can be adjusted within the RMF interval. This tool is helpful to determine the effect of paging and swapping on a given performance group.

RMF Monitor 1 provides two reports which include expanded storage activity. The RMF Paging activity report, Figure D, reports key indicators of expanded storage usage on the right side of the report. The paging values on the left side of the report are for auxiliary storage. The Swap Placement Activity report is also helpful in tracking the effects of changes, particularly if you are attempting to send pages to auxiliary storage. RMF Monitor II - The Address Space State Data (ASD) report includes an Expanded Storage

TABLE of OPT Parameters - Default values

Figure D

Frame (ESF) value. The Paging report (SPAG) reports migration rate and age values, expanded storage movement rate, and expanded storage available.

THE TUNING EFFORT

The system activity, before any keyword settings, is presented in Figure E. Note the rate of page movement to expanded storage and the migration age. Note also the paging activity reported. Hundreds of parameter combinations could be tested, fifteen OPT settings were implemented and observed, seven were selected for discussion. Data on these different settings is reported in Appendix A. Each setting is referred to as a case with Case 0 being the initial condition of the system before any OPT changes were implemented. The data for Case 0 is in Table 0A of Appendix A and for Case 1 in Table 1A and so on. The data presented in Appendix A was averaged for the intervals for which the keywords were in effect. A number of observations for each setting were recorded during peak periods. A general discussion will be presented here for each case.

Three OPT settings were implemented for n=1, or 'all other' category and are presented in Case 1 - Case 3. Case 7 includes both the 'all other' and TSO and is discussed with the TSO settings. The terms BATCH and 'all other' both refer to n=1.
In Case 1, the keywords in effect were for changed and unchanged page-outs. This setting had no apparent impact to the system in general. The number of batch initiators was reduced to six and therefore the batch load on the system was light. It should be noted that when (n) is 1, batch (ie. PGN 1) may not be the only jobs which are affected. Determination of what address spaces are classified 'all other' is important to avoid unexpected degradation. The CPU utilization was low in Case 1 and batch throughput was fairly good. Minimal paging was observed for the batch jobs. The overhead decreased from 26% (Case 0) to 17%. Note that the migration rate remained high and the page move rate to expanded was reduced over Case 0.

In Case 2 the keywords in effect were for changed and unchanged swap pages and for working set pages. The impact to the system was minimal. The overhead decreased from 26% (Case 0) to 20%. The migration rate was less as was the page movement rate to expanded storage. CADD first period response time increased by .1s.

In Case 3 both swapping and paging keywords were in effect. The overhead increased from 26% (Case 0) to 27%. The response time for the paging packs doubled. CADD first period response time increased by .2s.

Three OPT settings were implemented for n=2, or TSO, and are presented in Case 4 - Case 6.
In Case 4 the page-out keywords were in effect. Due to the direct use of auxiliary storage there was considerable less expanded storage page movement. The migration rate was less due to the reduced demand for expanded storage, and the MVS overhead decreased from 26% (Case 0) to 19%. CADD first period response time was increased .3s.

In Case 5 swap keywords were in effect. The impact of sending swap trim and swap working set pages to auxiliary storage was quick and severe. As shown in Table 5A the response time is twice its normal value. A large amount of the reported value is spent in page-in waits. The MVS overhead increased from 26% (Case 0) to 30%. The migration rate for this interval was zero. Since pages were being sent directly to auxiliary, the demand for expanded storage was decreased, therefore, there was no need to migrate pages to free up expanded storage to meet the demand.

In Case 6 both the page-out keywords and the swap keywords were implemented. As in Case 5, the impact of this OPT setting was immediate and severe. First, all paging and swapping activity went to auxiliary storage. Since no swap datasets exist the page requests were delayed by the swap activity. The number of local paging devices had been reduced when we brought in expanded storage, so the current configuration was not able to handle the increased load. These delays were noticeable to all users. CADD period 3 was most noticeable since they were swapped in this period. Although this setting was only on the system for a few minutes, calls came in from users about response time. According to DEXAN, 30% of the response time was due to page-in waits. (the page-in waits reported are only auxiliary page-ins) The MPAG command revealed the CADD users paging rate as high as 524 pages/sec. The paging device activity is reported in Appendix A. This activity appears to be due to the swapping which is going to auxiliary storage. Since the swap trim is greater, more paging is experienced. Although users do not experience swap out delay, the lack of swap data sets was again a factor for the page-outs/ins, which the user did experience. The MVS overhead increased from 26% (Case 0) to 29%.

In Case 7 all BATCH pages and page-outs for TSO went to auxiliary. This setting had the effect of disengaging expanded storage for BATCH. The expanded storage move rate was considerably reduced, the MVS overhead decreased from 26% (Case 0) to 25%. The response time for BATCH and TSO increased significantly. Period three response time was extremely high as users are effected by the demand on auxiliary storage and the batch swap-outs to the paging devices. In Case 7 the migration age value was observed through OMEGAMON to change at the approximate rate of 1.5sec. per sec. This generally occurred when the migration rate was zero, however, it was also observed when migration was taking place. This same rate of change in the migration age was observed in Cases 3, 5, and 6. In the other Cases the migration age would remain constant for several moments, change, then remain constant for several more minutes.

CONCLUSION

Many OPT settings were tested, most of which would not be implemented since the purpose of expanded storage is to reduce delays caused by paging and swapping. The purpose of the settings was to gain a better understanding of how expanded storage works. Two of the settings, Case 1 and Case 2 were used in the CADD environment, with Case 1 providing the best trade-off in CPU usage and performance of the online system. In general, the amount of CPU cycles gained due to reduced MVS overhead is not worth the cost of online degradation. This author found that Migration Age is a somewhat erroneous value. It seems odd to set a Criteria Age based on a value that is not an actual count or time but a calculated value (by SRM). More documentaion is needed on how migration age is determined and adjusted. The current keywords in the OPT are far too broad to offer much control, sort of an all or none choice. A preferred option would be to select the type of user, based on performance group, jobname or address space, to use auxiliary storage and not expanded.

SUMMARY

A brief description of expanded storage and some key terms and concepts have been presented. Some of the tools available which offer visibility into expanded storage use have been discussed. A tuning effort using the OPT expanded storage keywords was presented. The conclusion of this author is that little control exists for expanded storage and setting the available parameters in the OPT for the CADD environment were effective in some ways and degrading in others. Better controls of expanded storage are required for its future cost effective use.

MEASUREMENT AND ANALYSIS OF EXPANDED STORAGE IN IBM 3090-400 SYSTEMS

Jeffrey P. Buzen
J. William Mullen
Annie W. Shum

Abstract

This paper presents a set of measurements which characterize expanded storage performance under varying loads. The measurements, which are based on a 3090-400 system operating in a heavy TSO environment, illustrate the nature of page migration and its effect on overall performance. The role of the Expanded Storage Criteria Table in controlling access to expanded storage and migration to auxiliary storage is also discussed.

OVERVIEW OF EXPANDED STORAGE

Expanded storage is one of the most important new features of the IBM 3090 architecture. Essentially, expanded storage can be regarded as an ultra high speed paging subsystem. When the real storage manager (RSM) decides to move a page out of central storage, the page can go either to a conventional auxiliary storage device or to expanded storage. Similarly, when a page must be brought into central storage, it can come from auxiliary storage or from expanded storage.

As this description indicates, expanded storage can only be used for 4K block transfers to and from central storage. Individual bytes in expanded storage cannot be addressed directly, and direct I/O transfers between expanded storage and conventional auxiliary storage cannot occur. Figure 1 illustrates the way expanded storage is integrated into an IBM 3090-400 system.

Since access to expanded storage is controlled by the RSM, expanded storage is not directly visible to user programs. Thus, expanded storage may affect the execution time of a user program, but in all other respects expanded storage is completely transparent to the user.

One very important aspect of expanded storage is its synchronous mode of operation. Apparently, two special instructions have been added to the 3090 instruction set to facilitate movement of page frames to and from central storage. The RSM executes these instructions to cause transfers to occur. In contrast with conventional I/O operations to auxiliary storage devices, the CPU is busy during the entire transfer, and no attempt is made to switch the CPU to another instruction stream while the transfer is being carried out.

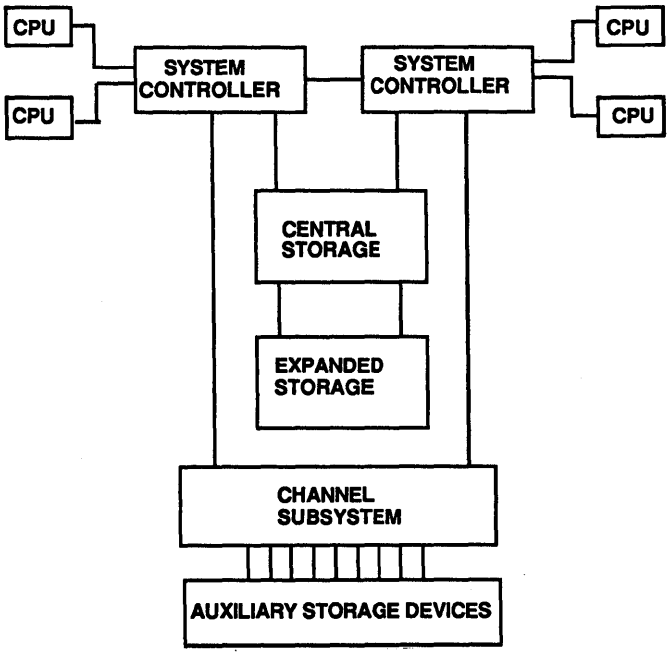

Figure 1

The time to resolve a page fault for a page located in expanded storage has been reported to be approximately 75-80 microseconds [1]. This compares with an expected time of 2-20 milliseconds to resolve a page fault from auxiliary storage. In a swapping operation where many pages are being transferred at once, the time per page is reported to remain at 75-80 microseconds. In either case, expanded storage transfers are more than an order magnitude faster than transfers to auxiliary storage. There is also a saving in processor overhead for I/O initiation and subsequent handling of the I/O completion interrupt.

One important reason for the development of expanded storage is the need to extend the addressability range of the MVS/XA architecture. Conventional storage with 31-bit addressing is limited to 2 gigabytes (2K megabytes) of addressability. Expanded storage is page addressable with 32-bit addressing. This allows for a 16K gigabyte addressing range, which is 8K times the addressability of central storage.

Other factors have also influenced the decision to develop expanded storage. One consideration is that expanded storage is less costly to fabricate since: addressing is at the 4K block level; there is no direct I/O to conventional auxiliary storage; there is no memory protection hardware. Also, error detection and correction has been enhanced by increasing the number of bits used for this purpose. This factor becomes more important as storage size increases.

EXPANDED STORAGE IMPLEMENTATION

Each new feature implemented in hardware or software brings with it the potential need for changes in resource management algorithms: usually new rules and new parameters are provided to control the use and operation of each new facility. Expanded storage is no exception.

One important change that expanded storage has initiated in MVS is the introduction of a page migration mechanism. To illustrate this mechanism, suppose the RSM decides to remove a page from central storage at a time when there is no space available in expanded storage. In the past, MVS would have sent that page to the next fastest auxiliary storage device. This alternative is still available. Now, however, MVS also has the option of removing old pages from expanded storage and writing them out to auxiliary storage to make room for new outbound pages. This movement of old pages is known as page migration.

Page migration represents additional overhead since pages that were originally sent to expanded storage have to be transferred back into central storage before they can be written out to an auxiliary storage device. In effect, migration adds approximately 150-160 microseconds of CPU overhead per page (i.e., one round trip between central and expanded storage). However, page migration can also provide a substantial benefit by maintaining in expanded storage those pages that have been least recently used and thus are most likely to be referenced again.

As already noted, two choices are possible if pages are being removed from central storage at a time when expanded storage is nearly full: either send the outbound pages directly to auxiliary storage, or send them to expanded storage and initiate a migration. MVS allows system programmers to influence this choice and provide certain types of pages preferential treatment in their access to expanded storage.

The choice is influenced through the IEAOPTxx parameters in the Expanded Storage Criteria Table. To describe the role of this table, it is necessary to review the definitions of two important indicators of storage utilization: the unreferenced interval count (UIC), which measures contention for central storage, and the migration age (MA), which measures contention for expanded storage.

UNREFERENCED INTERVAL COUNT (UIC)

The primary indicator of contention for real storage in MVS is the page unreferenced interval count (UIC). A separate UIC value is maintained by the System Resources Manager (SRM) for each occupied real storage page frame. Updating of the UIC values is based upon reference and usage of the frame. At initial allocation of a real storage page frame, the UIC value for that frame is set to zero seconds. As the SRM reviews usage of real storage frames, the UIC value for a given frame is increased by the number of seconds that have elapsed since the frame was last referenced.

To enable the UIC values to drive various MVS memory management algorithms, two additional values are calculated. The system high UIC is the largest of the UIC values in the system at any given instant. For an interval of time, the corresponding measure of contention is the average system high UIC. If these values are large, then contention for real storage is low since, on the average, page frames may remain allocated and unreferenced for long periods of time without being stolen or swapped, and without creating a real storage frame shortage. Similarly, a low value of the system high or average system high UIC indicates that contention for real storage is high.

MIGRATION AGE (MA)

The availability of expanded storage in 3090 processors created a requirement for additional measurements to determine expanded storage utilization and to provide a basis for access to this resource. The primary indicator used to support these functions is the Migration Age (MA). The only information currently provided by IBM on the calculation of migration age is the general statement that migration age represents the average page life of a page residing on expanded storage.

We can derive inferences regarding migration age from the measurement data available in RMF and other sources. First, migration age appears to be a global value rather than set of individual values computed separately for each expanded storage page frame. This assumption is based upon the fact that, at the first occurrence of migration, the migration age is reduced dramatically. The calculation of migration age may be based upon the amount of time that elapses between occurrences of migration and the average number of frames occupied in expanded storage between these occurences. This is analogous to calculations made by VM/370 memory management algorithms.

The migration age value is not limited to the 255 maximum imposed upon the UIC values. Migration age values in the hundreds of thousands have been observed in MVS/XA systems, provided these systems have been operational for extended periods of time and there has been no migration of expanded storage pages to auxiliary storage.

RMF provides measurement interval averages for migration age and also provides the ability to trace the migration age value via the MCVMGAGE trace keyword. Analysis of RMF traces during periods when no migration was occurring has indicated that migration age increases at the rate of 1.5 seconds for each wall clock second of elapsed time. This method of increasing migration age would account for the sizable migration age values observed in systems that processsed for extended periods of time without experiencing migration.

USE OF UIC AND MIGRATION AGE

The rules used by MVS to manage expanded storage usage and page migration allow different categories of pages to be treated differently. One of the factors used as a basis for different treatment is class of storage. The classes are defined as follows:

Class	Description
0	Non-swappable, Common and Privileged
1	All Others Not 0 or 2
2	TSO Swap and TSO other

These classes of storage are used as column headings in a new table, the expanded storage Criteria Table (ESCT), as shown in Figure 3. Algorithms operating on this table determine eligibility for transfer of a task's pages to expanded storage. This table is analogous to the Logical Swap Control Table (LSCT) implemented with the logical swapping facility in MVS.

For non-swap pages (rows 1 and 2), stolen pages (rows 3 and 4) and IMS virtual fetch pages (last row), the current value of Migration Age must be greater than the Criteria Age (MA > CA) that appears in the appropriate row and column of the ESCT for the page to be eligible for transfer to expanded storage. The objective of this basic rule is to prevent expanded storage migration if there is contention for expanded storage frames (as indicated by a low migration age).

For swap pages that are not terminal wait pages (rows 5-7), the UIC plus the Migration Age be must be greater than the appropriate ESCT Criteria Age (UIC + MA > CA) for the page to be eligible for transfer to expanded storage. In this case, increased contention for real storage (indicated by low UIC) can cause pages to be sent directly to auxiliary storage even though contention for expanded storage is only moderate. In other words, non-swap pages can be given preferential treatment over swap pages when contention for real storage increases grows.

For swap pages that are terminal wait pages (row 8), the UIC plus the Migration Age minus the user's 'think time' must be greater than the appropriate ESCT Criteria Age (UIC + MA - TT > CA) for the page to be eligible for transfer to expanded storage. Since think time is subtracted from UIC + MA, this rule gives preferential treatment to TSO users who have shorter think times.

The Criteria Ages are specified in the IEAOPTxx member of SYS1.PARMLIB. Each of the parameters are prefixed with ESCT and have three values corresponding to classes of storage 0, 1 and 2. The parameters and their abbreviations are listed below in Figure 2.

Paged-out Changed	(POC)
Paged-out Unchanged	(POU)
Stolen Changed	(STC)
Stolen Unchanged	(STU)
Swap-out Changed	(SWC)
Swap-out Unchanged	(SWU)
Swap Working Set	(SWWS)
Virtual Fetch (IMS)	(VF)

PAGE TYPES AND THEIR ABBREVIATIONS

Figure 2

Each of these eight page types is assigned three criteria ages, corresponding to the three classes of storage. These criteria ages are then used in determining eligibility for use of expanded storage. The structure of the ESCT and the default criteria ages (in seconds) are shown in Figure 3.

From the default values, it can be seen that MVS/XA stolen pages for common and privileged users are the most favored pages for use of expanded storage. The next favored class includes virtual fetch pages as well as stolen working set pages for TSO users.

Very little has been published to provide guidelines or recommendations on possible changes to the OPT default values in the ESCT. However, early experience indicates that very large changes in these values are required if there is to be any real impact on performance.

CRITERIA TABLE

	Storage Class Priv 0	1	TSO 2	Criteria for Transfer to Expanded Storage

VIRTUAL FETCH				
IMS Only		15		UIC+MA > CA

Figure 3

CASE STUDY

We have discussed the basics of the IBM 3090 architecture and the implementation of expanded storage. We will now examine some actual measurement data and look specifically for indications of the 'Large Systems Effect'.

Our graphs are derived from measurement data obtained from a 3090-400 processor complex operating in single image mode. This complex has 128 megabytes of central storage and 256 megabytes of expanded storage. The primary workload, which is TSO, averages 520-560 logged-on users with approximately 380 of these users active at any given time. There is minimal batch processing allowed on the system. TSO is a production workload, and users tend to be slightly higher in their resource consumption per transaction than users in a TSO development environment would be.

The first chart in this series, Figure 4, illustrates the expected depletion of central storage page frames as the number of logged-on TSO users increases. The points on this and other charts are average values from several measurement intervals. A point of significance in the chart is the values for available central storage frames in the range of 150-170 logged-on users. The slight increase in available frames could be an indication that MVS/XA is beginning to page steal to replenish the available frame queue. An average value of less than 1000 frames is an indication that, during a majority of the measurement intervals, the available frame count was not sufficient to satisfy the demand for central storage.

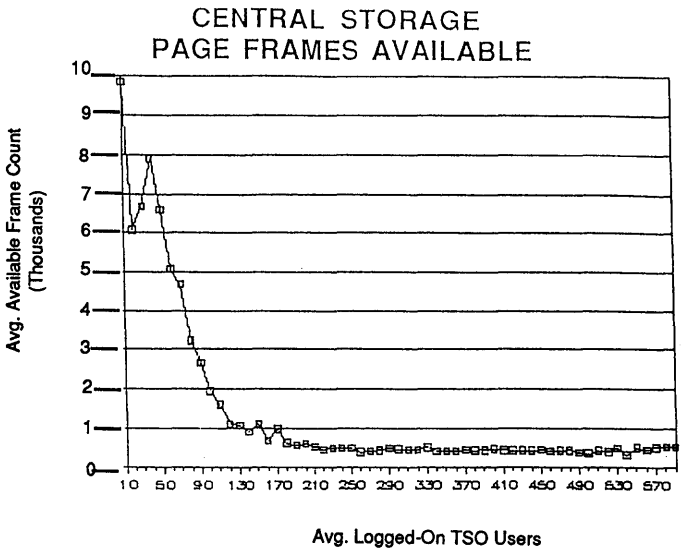

Figure 4

The transfer of pages from central storage to expanded storage is illustrated in Figure 5, Pages Per Sec To Expanded Storage. We note that transfers begin when there are approximately 100 logged-on users. This corresponds to the depletion of available central storage frames illustrated in Figure 4. This depletion would tend to decrease the amount of TSO logical swapping, causing more pages to be sent directly to expanded storage.

The availability of expanded storage frames decreases in concert with the increase in the pages per second sent to expanded storage. As discussed previously, migration is the mechanism used to regulate the number of available expanded storage page frames. Figure 6 illustrates the depletion of expanded storage frames as the number of active TSO users increases. As the number of logged-on TSO users increases, the number of swap sequences also increases leaving an ever increasing number of pages on expanded storage.

In Figure 6, we note a slight increase in the average number of available expanded storage frames with 190-200 average logged-on users. Based upon the measurement data, this is the point where the expanded storage frames are depleted to the extent that migration starts. Prior to reaching this level, we saw the depletion of central storage frames with 170-180 logged-on users. This caused a corresponding increase in the number of pages per second being sent to expanded storage. We can see the sequence of events occurring in MVS/XA's management of available storage resources and another cause and effect relationship in the MVS/XA operating environment.

As the number of available central storage frames decreases (Figure 4), we see an increase in pages per second sent to expanded storage (Figure 5) and a decrease in the available expanded storage frames (Figure 6). We now focus on the primary mechanism used by MVS/XA for managing expanded storage: migration.

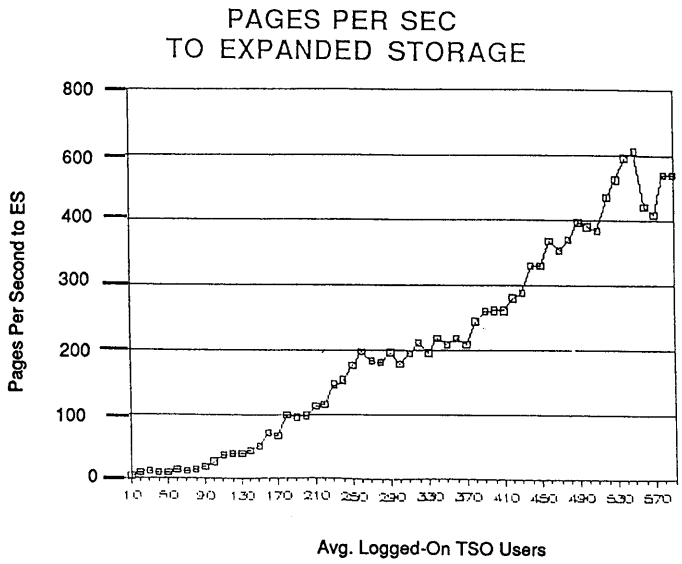

Figure 5

In Figure 7, we see the consequences of saturation on both central storage and expanded storage. We note no occurrence of migration until the number of logged-on users reaches 170-180. At this level we see a slight migration effort by MVS/XA which begins to replenish the expanded storage available frame queue. This is the Real Storage Manager's migration appetizer. The main course is served at the 200-210 logged-on user level and increases continuously until the system reaches 250-260 logged-on users. The next surge of migration activity occurs at 370-380 logged-on users. At this point, the average Migration Age will remain low indicating substantial contention for expanded storage. This results in continuous migration of expanded storage frames to auxiliary storage.

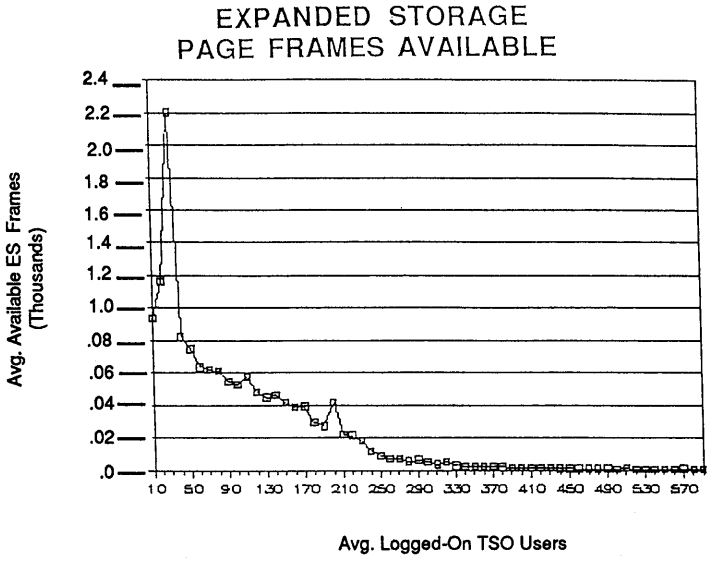

Figure 6

Another cause and effect relationship from MVS/XA memory management is shown in Figure 8. As MVS/XA begins page steal operations to replenish the central storage available frame queue and, subsequently, as migration activity begins to replenish the expanded storage available frame queue, use of the 3090-400 processor is affected. We see in Figure 8 a slight increase in processor utilization occuring at 170-180 logged-on users as MVS/XA begins migration operations to replenish the expanded storage available frame queue. The increase is due to extra processor overhead required by the migration process.

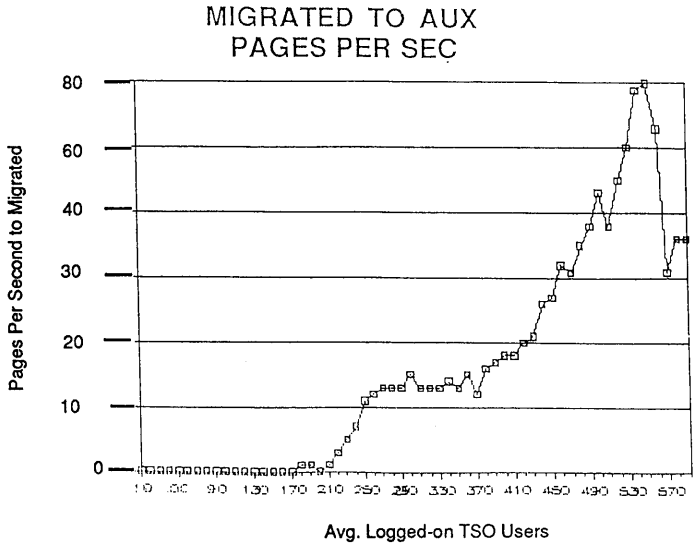

Figure 7

At 200-210 logged-on users, full scale migration of expanded storage pages to auxiliary storage begins. We again see an increase in processor utilization due to extra migration overhead. We can deduce from the graphs that MVS/XA page steal operations and expanded storage migration can have a negative impact on workload throughput and access to processor resources.

On some 3090-400 processors where the active number of address spaces exceeded 700-800, degradation was severe during MVS/XA page steal and migration operations. This problem was alleviated by APAR AY01085 which modified the MVS/XA page steal algorithms to replenish available page frames below the 16 megabyte line if there is a shortage in this region. This APAR has been superseded by PTF UY90024 and is available only for 3090-400 processors. We also see from the charts that once MVS/XA goes through the initial trauma of page steal and migration, these operations seem to smooth out as long as the workloads on the processor remain fairly stable. From Figure 8 we also see that the processor is not consistently saturated until we reach 490-500 logged-on users.

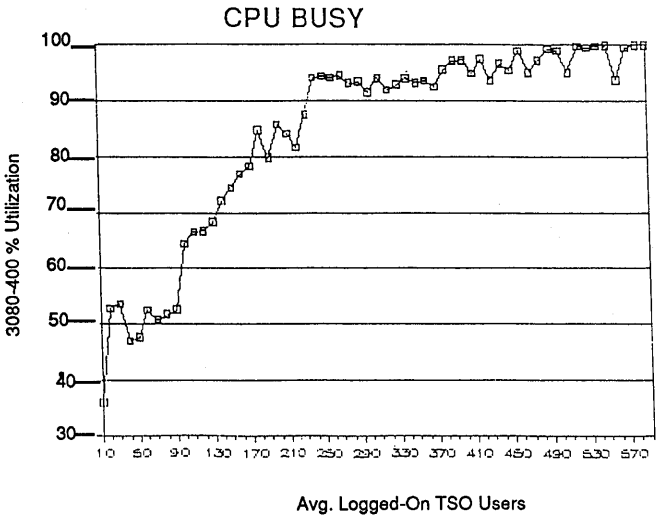

Figure 8

In Figure 9, TSO Throughput, we see that the transactions per second throughput rate does not appear to be adversely affected by MVS/XA page steal and migration operations on this processor. This has not been true on other 3090-400 processors that we have analyzed. We can surmise that the 'Large Systems Effect' is not as pronounced on processors where one type of work, such as TSO, is the predominant workload. Where there is a mixture of TSO and batch workloads on a

processor, batch requirements for central storage and expanded storage frames could have a substantial impact on the performance of the TSO workload. This would specifically be seen due to batch workloads having a greater demand for central storage page frames below the 16 megabyte line and an increase in MVS/XA page steal operations.

Though we did not see a significant impact on the TSO transaction per second throughput rate in Figure 9, the chart in Figure 10, TSO Response Time, provides more insight on the impact that MVS/XA page steal and expanded storage migration can have on a TSO workload's performance.

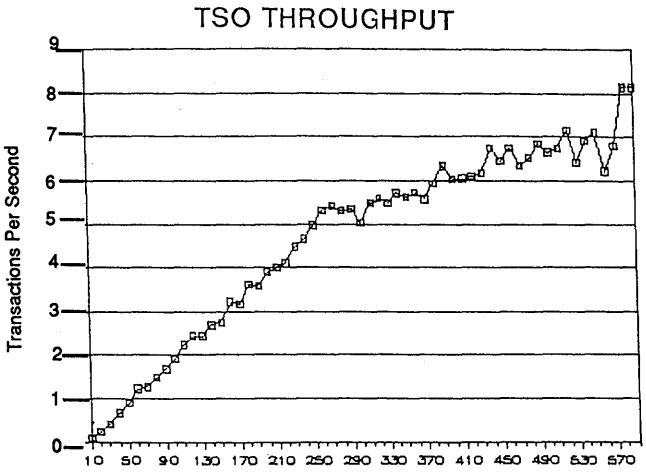

Figure 9

The sudden increases in the period one TSO transaction response times as shown in Figure 10 may be the result of MVS/XA page steal and migration operations, but viewed from a different vantage point. At lower numbers of logged-on users (less than 100), processor utilization and transaction throughput rates may not be as adversely affected by MVS/XA page steal and migration activities since any shortages of central or expanded storage would not be significant or prolonged with this smaller number of logged-on users. Also, LOGON activity will have a more pronounced effect on average response times with so few logged-on users.

Points of interest on the TSO Response Time chart are between 180-200 users and 210-240 users. At 180-200 logged-on users, we observed indications of MVS/XA page steal operations as central storage frames were depleted. At 210-230 logged-on users, we observed indications of expanded storage migration beginning to replenish expanded storage available frames. The TSO response times during these load levels reflect what could be the results of MVS/XA page steal and migration activities.

Consider next the 430-460 logged-on user level shown in Figure 10. The spikes in period one response times may be attributable to DASD delays (for user I/O) due to increased DASD activity from a larger number of users. Alternatively, they may be due to IPS MPL constraints. In either case, we would expect to see the trend continue and get progressively worse.

Clearly both MVS/XA page steal and expanded storage migration have many effects on throughput rates and response times. This is an area that needs a substantial amount of additional analysis. The 'Large Systems Effect' brought on by the increased number of active address spaces on the 3090-400 processor complex has revealed itself primarily in the area of storage management. With the announcement of the 3090-600E processor complex and the ability to operate with an even greater number of active address spaces, memory management and the demand for central storage frames below the 16 megabyte line may require extensive changes in the MVS/XA memory management algorithms.

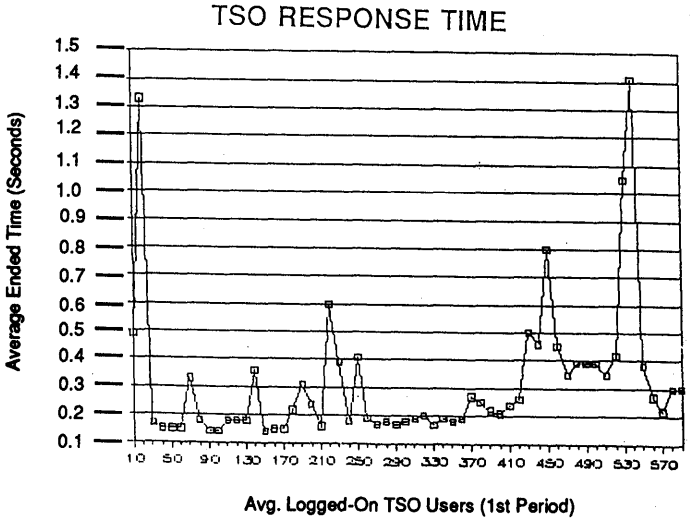

Figure 10

SUMMARY OF INTERACTION

We can summarize the interactions illustrated by the charts in Figures 4-10 with the following:

- Increase Number of TSO Users;
- Decrease Available Central Storage Frames;
- Trigger Movement of Page Frames to Expanded Storage;
- Reduce Available Expanded Storage Page Frames;
- Trigger Migration of Expanded Storage Frames to Auxiliary Storage; and
- Increase Processor Overhead to Support Migration.

The interactions have a net impact of:

- Throughput Rates Can Decrease;
- Response Times Can Increase.

The degree to which the net impact is felt will vary with memory constraints and task working set characteristics for the workloads being processed.

EXPANDED STORAGE CONSIDERATIONS

Expanded storage has helped alleviate many of the paging and swapping problems experienced by some installations.

Large TSO installations have received the greatest benefit from expanded storage due to the reduction in swap-in delay ('wait-to-start') time. Swapping is the primary mechanism for controlling TSO user access to resources, and swaps to expanded storage can be more than an order of magnitude faster than swaps to conventional auxiliary storage devices. This reduction in swap-delay time can provide improvements in both transaction throughputs and transaction response times.

TSO logical swap has been the previous mechanism for providing TSO period one users with required response times, often in the sub-second range, and for preventing swapping to auxiliary storage. With the availability of expanded storage, TSO logical swap should not be turned off (LSCTMTE = (0,0)) but may possibly be reduced. The

enhanced speed with which TSO swapping can occur through the use of expanded storage allows the freeing of central storage page frames (once used to hold logically swapped users) without suffering the swap-delays from auxiliary storage. It should also be noted that the 'think time grace period' for logically swapped TSO users was reduced from 15 seconds to 2 seconds in Release 2.1.3 of MVS/XA.

The Expanded Storage Criteria Table (ESCT) values in the IEAOPTxx member of SYS1.PARMLIB can be adjusted to bias the use of expanded storage for TSO, Batch or IMS/VS Virtual Fetch. The reader is cautioned that no guidelines have been made available by IBM for changing the ESCT constants or for providing a rationale for the default values illustrated earlier in this paper. Changes to the ESCT values should be made one at a time, and the effect of each change on workload throughputs and response times should be analyzed thoroughly before making additional changes.

The final benefit of expanded storage is a reduction in the utilization of channel paths and devices due to reduced paging and swapping activity to auxiliary storage. For many installations, this reduction has enabled installations to recover a significant amount of channel path, DASD controller and device capacity. Reducing paging and swapping device 'spread' has also allowed many installations to reconfigure their I/O subsystems and enhance overall I/O performance.

A note on paging data sets. Virtual storage backing for address spaces is still required in local page data sets until the availability of MVS/XA Release 2.2. Some installations have reduced the size of their local page data sets or eliminated local page data sets only to find that the virtual backing was still required and that page slot shortage messages are still issued by MVS/XA. Page slot shortages will prevent the creation of new address spaces.

CONCLUSIONS

Expanded storage can provide a substantial improvement in the overall performance of MVS systems, especially heavy TSO environments. However, as the number of TSO users increases, total available processor storage (central plus expanded) will eventually saturate and migration overhead can become a problem.

The IEAOPTxx parameters in the ESCT can, in principle, determine which classes of users suffer the most or least from migration overhead. In practice, substantial changes in these parameters produce only minor changes in relative performance. These parameters may, however, be of greater value in the future when additional facilities are introduced for the support of VSAM linear data sets, data in virtual, and special DB2 requirements.

A HEURISTIC MODELING APPROACH TO CICS CAPACITY PLANNING

Steven R. Hackenberg
Candle Corporation

ABSTRACT

Capacity planning for CICS has evolved from simple models and intuition to more sophisticated techniques which use a set of analytic models to calculate response time components of a transaction, such as network, device, and CPU times. Rarely do these models account for architectural limitations of CICS. This paper will focus on a simple model which considers the concept of software queuing as a starting point for projecting the effect of increases in current transaction volume and implementation of new applications.

INTRODUCTION

Consider the following scenario which will illustrate a common misunderstanding in data centers, and set the tone for the focus of this paper.

A large data center had 2 CPU's with workloads divided in the following way. System A was used to run TSO, production batch, and test batch. System B was used primarily to run the production CICS system with an insignificant amount of additional workload. System B was a 7.5 MIPS single-processor CPU running at less than 60% CPU utilization consistently during prime shift. Data center management was convinced that they could save a large amount of money by eliminating their excess capacity, so they swapped out System B and installed a 4.5 MIPS single-processor CPU. When the production CICS system was brought up during prime shift, response time had eroded from sub-second to 20 seconds, and during peak loads had become even worse. It became obvious that they had made a mistake but no one could understand the underlying reason. What they failed to consider was the simple concept of software queuing.

CICS ARCHITECTURE

To understand how software queing becomes an issue, a brief discussion of CICS architecture is appropriate. The primary purpose of CICS is to manage resources, such as terminals, files and storage, while performing services on behalf of transactions. Another major function of CICS is to control the execution and serialization of transactions as they request CICS services and execute application programs. The current status of each transaction at any instant in time will be indicated in the Dispatch Control Area (DCA), a control block created to mark the existence of a unit of work. All the services performed by CICS are divided between MVS (or DOS) tasks as illustrated in figure 1. Some services performed, such as a request for record journaling, are executed under a separate Task Control Block (TCB). A key point is that all serialization activities and application program execution is performed under the umbrella of a single TCB, shown in figure 1 as the on-line TCB. The outcome of this architecture is that the bulk of the work performed by CICS, thus the vast majority of the CPU consumed by CICS, is done by a single server element. This leads naturally to the potential for software queuing.

PREDICTING SOFTWARE QUEUING

Understanding the degree of software queuing in the context of CICS can be expressed in the following way. What is the probability that at any instant in time, more than one transaction, or DCA, will be in a ready status. To further define this concept, let's look at it from an operating system viewpoint. The CICS workload either has work to be performed (ready), or it does not (not ready). Given the availability of the CPU resources, CICS in a ready state, and the lack of a higher priority workload (i.e. operating system page handling, VTAM, etc.) CICS will be given control. Any attempt to monitor CICS from an operating system standpoint will only show the availability of the CPU resource, and CICS's ability to exploit it. This leaves three possible conditions: 1) CICS ready (or actually executing); 2) not ready; 3) ready, but unable to run because of pre-emption by a higher priority workload (waiting for CPU). The capability to detect software queuing within a CICS environment does not exist within an operating system monitor because it can only see CICS's ability to exploit the CPU resource, but not to what theoretical depth.

Just as competing workloads being controlled by an operating system can wait on CPU, transactions competing for machine cycles on a dispatch chain within CICS can be hindered by other transactions. Having one CICS transaction on a DCA chain in a ready status, all succeeding ready transactions can be thought of as waiting on dispatch. The reason that Wait-On-Dispatch is considered a software queue is because the architectural limitations of a single CICS address space precludes the ability to make effective use of a multi-engine CPU complex such as a 3090 model 400.

The actual prediction of Wait-On-Dispatch is directly related to the aggregate consumption of CPU cycles by the CICS workload itself and all higher priority workloads. Experience has shown that typically when total CPU consumption of CICS, and higher workloads, remain at less than 40%, the amount of Wait-On-Dispatch is negligible. Once this total workload begins to exceed 50% CPU utilization, Wait-On-Dispatch becomes significant and in fact accelerates rapidly. The degree of acceleration is dependant on the capacity of the CPU as shown in figure 2. This diagram is for illustrative purposes only. The actual point of acceleration will be dependant on factors such as the profiles of the transactions running on the particular CICS system. For example, a CICS system which has short application program path lengths with a high number of file accesses, and VSAM subtasking in effect on a dyadic processor, may move the acceleration point beyond the expected norm.

DETECTING WAIT-ON-DISPATCH

Most CICS monitors in existence today do not detect Wait-On-Dispatch. They fail to see this condition because they are event driven, typically from the CICS trace facility. To illustrate, let's consider a transaction in execution fairly low on an active DCA chain which requests a file access. A trace record is created indicating the call to File Control and the task is marked not ready. When the File Control request is completed, CICS will mark the DCA for the task as ready to run on the next DCA search, but no trace record will actually be created until the task is re-dispatched. In an over committed CICS environment, the length of time between completion of a file control request and a re-dispatch could easily be more than half of the total transaction response time.

The most practical way to detect Wait-On-Dispatch is by using a sampling technique where the active DCA chain is interrogated at fixed time intervals. An interval of 2 seconds works well to accumulate counts for total active tasks and task queuing. Because of the asychronous processing design of CICS, the DCA will not be updated until DCA search time; therefore, the analyzer will have to determine if the ECB associated with the DCA has been posted complete. The data should be logged for later analysis, and the accumulators should be zeroed out on a periodic basis, such as every 30 minutes, so that the degree of Wait-On-Dispatch can be measured for various times of the day. If you do not have a monitor which will report Wait-On-Dispatch statistics you can write one with some effort. The accumulated numbers should be put into the following formula:

$$\frac{\text{Total Ready Tasks After First}}{\text{Total tasks found on Active Chain}} = \text{Wait-On-Dispatch as Percentage of Response Time}$$

In the absence of a monitor which is sensitive to the existence of Wait-On-Dispatch, users can predict, with some accuracy, the acceleration point based on intuition. The simple fact is that as CICS and higher priority workloads begin to move beyond 50% total CPU utilization, the probability of software queuing is large, and the rate of acceleration of degredation due to Wait-On-Dispatch will increase as aggregate CPU consumption continues to increase.

Going back to the original case study, additional conclusions can be drawn from our scenario. Even though total CPU consumption was at 60%, about 50% of it was attributable to CICS and MVS related overhead. Software queuing had probably started to occur significantly. By down sizing the CPU from 7.5 MIPS to 4.5 MIPS, they increased aggregate CPU to above 75%. Had they fully understood Wait-On-Dispatch, they would have known that response time would suffer drastically in this situation. As it turns out, the monitored Wait-On-Dispatch was consistently greater than 68% of response time, and the execution phase of response time was running at about 30%, a significant increase due to the slower CPU speed.

MOVING THE ACCELERATION POINT

In a multi-engine CPU complex, there is a simple technique which can be used to move the acceleration point and thus devote more CPU capacity to CICS without degrading response time. The solution is simple--make use of the MRO capability offered by CICS. To reiterate our previous discussion, the primary cause of software queuing at such a low CPU level is due to the single server element restriction in the CICS architecture. The easiest way to solve this problem is to create a multi-server element environment for a given CICS workload. Let's consider an ideal situation. We have a 3084 quadratic CPU complex. We create an MRO environment with a Terminal Owning Region (TOR) and three Application Owning Regions (AOR's), dividing our application volume equally between the three AOR's. What we have accomplished is that we now have four servers for the same CICS workload. To further define our ideal situation, we have created four online TCB's controlling four DCA chains, all of which can be simultaneously dispatched on the four engines of our 3084 CPU complex. Theoretically we have created an environment which will allow CICS to exploit all 100% of our 3084 with no appreciable degradation due to Wait-On-Dispatch.

Now let's set aside our "ideal" and consider reality. The TOR itself will consume far less than 1/4 total CPU. Its basic function will be to read screens and hand off transactions to the AOR's, and receive and redisplay screens from the AOR's. In a large CICS network, chances are good that the TOR will occasionally have multiple screens to process at the same time and, as a result, become a bottleneck. Also, MRO does not come for free. There will be a certain amount of overhead associated with managing the shifting of transactions to other address spaces, and the potential exists for an increase in real storage commitment. Using this approach, the acceleration point for Wait-On-Dispatch before a noticeable erosion in response time is probably above 70% total CPU. At the very least, MRO in a multi-engine CPU complex offers some flexibility.

CONSIDERATIONS MOST OFTEN FORGOTTEN

Certain pitfalls exist that are easily forgotten which can effect the amount of Wait-On-Dispatch experienced. Mentioning a few of these will give users a feel for what to look for when response time degrades due to software queuing when there is no appreciable increase in CICS volume.

VM

Running a CICS system under MVS (or DOS) under VM will almost guarantee a 20% Wait-On-Dispatch. (The 20% figure is the most common one seen in the field.) This really makes sense when you think about it. VM itself will carry 10-20% overhead just by the nature of what it does. Next, you have an operating system and related overhead taking 15-20%. The presence of VM will cut down on the amount of available real storage causing even more overhead. The net result is that we already have about 40% of a CPU being consumed above the CICS workload, and we have not yet considered the CPU being consumed by CICS itself. Even with a moderate CICS system taking 15% of a machine, we have probably gone past the point were software queuing becomes a problem.

PAGING

Many people have fallen prey to Wait-On-Dispatch because of total system wide paging. Users can assure that CICS itself does very little paging by using storage isolation. But, if total paging in the system gets out of hand the operating system overhead to process damand paging will begin to drain valuable CPU availability by increasing aggregate CPU consumption above the CICS workload.

VTAM, JES2, ETC.

Although typically the service address spaces, such as GRS, VTAM, JES2, CATALOG, etc., consume very little CPU, there are occasions when this becomes a problem. In this case users should consider moving JES2 below the CICS workload in priority but, the point is to make sure you understand the total CPU being consumed by these service processors.

CLASS MAX TASK (CMXTSK)

Due to application design limitations, or other reasons, users sometimes have a requirement to use CMXTSK to control certain applications. Prior to CICS 1.7, CICS attempts a conditional attach of any transaction which has been classed so that task control can assure that the class limitation can be honored. CICS will re-attempt the conditional attach for transactions deferred due to Class Max, based on the Scan Delay value of 0 milliseconds. In some cases heavy use of CMXTSK has caused over 10% CPU to be consumed just because of a high number of attempts to attach. This problem is easily solved by setting scan delay to 500 milliseconds or more.

SUMMARY

Many data centers have fallen into a false sense of security when considering the capacity requirements to support a CICS system. How many of us have heard the cry "Hey, no problem. Bring on that new application, we have PLENTY of CPU." A large number of people just do not realize that long before CICS can exploit 100% of a CPU, software queuing will potentially degrade response time far beyond acceptable service levels.

The first step to take is to understand the current CICS workload and the CPU utilization of all higher priority workloads. With an awareness of software queuing and the point at which it will most probably begin to become a serious problem, users will be in a far better position to accurately predict their CPU needs. This heuristic approach has the advantage of being based on the actual environment without the need to make assumptions, and it is an approach which everyone can easily understand.

PAGING ANALYSIS IN AN EXPANDED STORAGE ENVIRONMENT.

Thomas Beretvas
International Business Machines Corporation,[1]
P.O. Box 390, Poughkeepsie, NY 12602

ABSTRACT

Multiple Virtual Storage (MVS) processor storage management and paging algorithms are reexamined with an emphasis on 3090 environments with expanded storage. Page data set space allocation recommendations are given. Paging device performance characteristics are discussed and configuration guidance given. The state transitions to various swap states are defined and illustrated. A case study of actual RMF data is performed for a 3090 environment.

Methods are described to identify and solve paging problems.

INTRODUCTION

Multiple Virtual Storage (MVS) processor storage management and paging algorithms are reexamined with an emphasis on 3090 environments with expanded storage.

A previous publication [1] gave MVS/370 paging guidelines. This paper assumes the use of the MVS operating system using extended architecture (MVS/XA). MVS/XA paging guidelines were presented before in [2]. This paper further assumes the use of IBM 3380 paging devices with Device Level Selection. The emphasis of the paper is on IBM 3090 processor environments, with expanded storage, unless otherwise stated.

Page data set space allocation recommendations are given. Paging device performance characteristics are discussed and this results in an easy-to-use methodology, sometimes known as "rules of thumb" for establishing paging configurations.

The state transitions to various swap states are defined and illustrated. A case study of actual RMF data is performed for a 3090 environment.

Methods are described to identify and solve paging problems.

Why consider paging at all?

In the last few years there has been a growing emphasis on interactive response time. Fast, subsecond response time has become a key to productivity [3]. Analysis of MVS and VM operating system environments revealed that--in the past--paging delays represented a major component of the response time, especially when the response time was not very good. Often, as high as 60 percent of the response time for trivial transactions was attributable to paging delays.

Paging, as the key problem is rapidly disappearing for installations with adequate processor storage configurations. This is particularly true for IBM 3090 installations with expanded storage. Even for these installations there is still a need to size an adequate paging configuration. The paper provides guidelines for this task.

PROCESSOR STORAGE MANAGEMENT

The management of processor storage (i.e., central storage and expanded storage) must be understood if paging is to be understood. MVS manages processor storage in fixed size (four kilobytes) pages. In MVS multiple "concurrently" running programs contend for the same limited processor storage space. If expense did not matter, at least conceptually, enough processor storage could be provided to accommodate all competing programs. But money does matter, thus processor storage is sometimes limited in size even today.

In a system with only central (previously known as main) storage "competing" programs share this storage. Through the years paging strategies have evolved, all centering on keeping the "needed" pages in central storage while moving the unneeded pages onto direct access storage devices (DASD), which act as paging devices. The reason for this strategy was that megabyte for megabyte, DASD storage space is much cheaper than central storage, but if "unneeded" pages are suitably selected and moved to DASD, then central storage occupancy is significantly reduced, and the delay caused by pages retrieved from DASD does not occur frequently.

In a system with expanded storage unneeded pages from central storage are usually first moved to expanded storage; then unneeded pages from expanded store are migrated to DASD via central storage. Of course, any page that is referenced by a program, must be retrieved from expanded storage or DASD into central storage. Page retrieval from DASD may cause quite a long delay (20-30 ms) for the program; from expanded storage the delay would be much shorter, about 75 microseconds.

---

[1] Permission is granted to CMG to publish this paper. IBM retains its right to publish this paper elsewhere and distribute copies of it to whomever it chooses.

PAGING STRATEGIES

The paging strategies attempt to keep the "needed" pages in processor storage while moving the unneeded pages onto auxiliary storage devices (DASD).

The paging strategies are based on three basic principles:

- If a user becomes **inactive** (e.g., goes into terminal wait status), the system assumes that his pages are unlikely to be referenced in the near future. Thus, if there is a shortage of frames, all (or most) of the user's pages are removed from processor storage to DASD. This is called a physical swap-out. Swap-outs free many processor storage frames. This is the primary mechanism for controlling processor storage occupancy.

- MVS attempts to satisfy the processor storage frame needs of all executing address spaces by keeping their working sets [4] (loosely: the pages that are required for execution) in processor storage. Once this need is satisfied, MVS stops short of completing swap-outs, and does "processor storage swaps;" using **excess processor storage** to retain the "swap group" pages for idle address spaces. The swap-out process includes defining the set of pages most likely to be needed the next time the address space executes. This is called the "swap group," and it is an approximation of Denning's "working set".

  Retaining the swap group means that pages not belonging to the swap group receive less favorable treatment. These pages are "trimmed". Page trimming is the second, most frequently used method for freeing up processor storage.

- It is assumed that if an active user does not reference a page for a long time (e.g., 20 seconds) then the page is not required in central storage. From this, we can infer that the page will not be required in the near future, and can be "paged out", [2] and the processor storage frame containing it is thereby freed. Page-outs are therefore selective and are based on the length of time that a particular page has been unreferenced. Only a few of the pages belonging to a user are removed. Similar strategies are used for both central and expanded storage.

Processor storage swapping reduces the activity to the auxiliary storage devices and improves response time by eliminating the I/O delay that would be necessary to (physically) swap-in the address space when it is again ready to execute. The elimination of swap-in delay is often critical to meet response time objectives for highly interactive workloads such as TSO and CADAM.

"Processor storage swapping" is an extension of what used to be called logical swapping. **Logical swapping** retains the inactive user's pages in **central** storage. A shortage of central storage frames may force these pages to be moved into expanded storage, causing an **expanded storage swap**. Processor storage swap is therefore a generic name encompassing both logical and expanded storage swaps.

In converting a logical swap into an expanded storage swap, the system distinguishes between "primary" and "secondary" working sets. The primary working set contains fixed and local system queue area (LSQA) pages and the first page of each virtual segment; while the secondary working set is the remainder. (Analogously to the **two-stage swap** prior to the advent of extended swap in MVS release MVS/SP 1.3.0). The distinction between primary and secondary working sets is important. If there is a shortage of expanded storage frames, then these pages in expanded storage may **migrate** to auxiliary storage (DASD) via central storage. During and after the migration, the primary and secondary working sets **retain** their identity and are handled differently.

[2] This is called least recently used, or LRU strategy, and it is seldom invoked in a well tuned installation.

PAGING OPERATIONS

Until now we discussed processor storage management. If processor storage is insufficient to contain all pages required, then paging to auxiliary storage occurs. In the following discussion, it is assumed that paging DOES occur. Please note however, that with increased central storage sizes and virtually unlimited expanded storage sizes, paging should not be a problem in well-configured modern installations.

Four different paging operations to/from auxiliary storage are distinguished:

1. **Page-ins.** When a program is referencing a page which is not in central storage, it page faults. If the page resides on auxiliary storage, an asynchronous page fault occurs; prompting the operating system to retrieve the page. that page by itself, from DASD. While the page fault is resolved, the program waits until the page is obtained from DASD. During this time, other programs may execute. Note that while page-outs usually involve multiple pages being written to DASD, page-ins (page faults) usually result in single page reads.

   If the page fault references a page in expanded storage, this is resolved synchronously, i.e., the page is retrieved from expanded store without surrendering control of the processor to another program.

2. **Page-outs.** The obverse of page-ins are page-outs. It is likely that a paged-out page will be subsequently page-faulted back into central storage.

   In installations with ample expanded storage, page-outs to expanded storage occur in preference to DASD, to exploit the faster page fault resolution of expanded storage.

   In environments with constrained or no expanded storage, page-outs to DASD occur. To better use the paging DASD resources, page-outs usually cause multiple pages to be written out at one time. There are three different kinds of page-outs: page steals, swap trims, and migration page-outs.

   - Page steals. An example of "page stealing" is when old (long time unreferenced) pages belonging to active users are taken. This tends to occur only in case of central storage shortage. A maximum of 10 pages are stolen from a user at one time.

   - Swap trim. A typical example of swap trim is when **unreferenced** pages belonging to users who go from active to inactive state are taken. Trimming is not limited in size and may involve many pages of a user. The primary working set contains referenced pages, thus these pages are not trimmed.

   - Migration page-outs. Migration page-outs occur because the system "migrates" non-working set i.e., stolen or trimmed pages from expanded storage to auxiliary storage via central storage.

The page-out blocking factor to DASD is determined by the auxiliary storage manager (ASM), and it is set to a maximum of 30 for 3380s, i.e., up to 30 pages can be blocked in a channel program. Migrated pages and swap trimmed pages may be paged out with a blocking factor of up to 30. The stolen pages have a maximum blocking factor of 10, since the limit of one time page steals from an address space is 10. The number of pages actually blocked is a function of the number of pages actually taken by the real storage manager (RSM). Thus, e.g., assume that 44 pages were trimmed for an address space. Then two blocks of pages are created; one of 30 pages and another one of 14 pages.

Note that the algorithm attempting to obtain contiguous slots on auxiliary storage is NOT invoked for page steals, and migration page-outs. This means that while the central processing unit (CPU) overhead of multiple start subchannel operations and interrupt handling is avoided, the DASD write operation is not fully optimized (intentionally). The non-contiguous writes are required to avoid fragmentation of the disk space.

3. **Swap-outs.** Many users of these systems are interactive, whose typical activity pattern is a short interaction with the system, followed by long inactivity or think time. As an example, interactions of 300 ms duration are common which are followed by inactivity lasting from five seconds to several hours. For these long thinking users, it makes good sense to get rid of all their currently held pages; this is the physical "swap out." Pages selected for swap-out are pages of the swap group.

   Given ample expanded storage, swap-outs often occur to expanded storage, because the swap-in speed from expanded storage is about two order of magnitudes faster than from DASD. (Noting that the two kinds of swap-in operations differ significantly, one may get an idea of performance difference by observing that a swap-in of 12 pages from DASD may take 80 ms, while a swap-in of 12 pages from expanded storage may take less than 1 ms). If the available expanded storage is insufficient to accommodate swap-outs, then the swapped out pages are written to DASD. There is a general control mechanism which determines whether the the address space is important enough to be swapped out to expanded storage or DASD. The decision depends on the quantity of expanded storage available, or more specifically on the "migration age" (briefly described later).

   A set of swap pages written to an actuator by a single SSCH instruction is called a swap set. A swap-out to DASD usually results in the swap sets being written into contiguous set of slots. The rationale for this kind of allocation is that a successful request results in a single seek and no latency between pages, thereby minimizing device service time and utilization.

   When swap data sets are used for swap-outs, the swap data sets are preallocated into contiguous sets of slots ready to receive the swap sets. Thus, in this case the swap sets are always written contiguously by the inherent nature of swap data sets.

   When local page data sets are used for swap-outs, the situation is more complex. The ASM "contiguous slot allocation" algorithm attempts to find a set of contiguous slots on the data set. The search for contiguous slots can be quite costly in CPU time however. Simulation results indicated that this search should not be undertaken unless there is an abundance of unused slots on the device. As a rule of thumb it might be considered that the number of slots available on the device should be at least four times as high as the number of occupied slots, for this algorithm to be operational.

   In a system with expanded storage, most swap-outs to DASD are migration swaps i.e., the user's working set is first logically swapped, then the logical swap is converted into expanded storage swap, and last, the primary and secondary working sets are--separately--migrated to auxiliary storage via central storage. If swap data sets are used, all direct auxiliary swaps and migrated primary (but not secondary) working sets go to them. If swap data sets are not used, all swaps go to local page data sets.

4. **Swap-ins.** Swapped out pages are retrieved by swap-ins. Swap-ins from expanded storage result in getting the pages in the primary working set, and subsequently page-faulting on the pages in the secondary working set, as required.

   A swap-in from auxiliary storage results in a retrieval of all the swapped out pages i.e., the previously written swap group of swap sets for this address space is brought back into processor storage. The system attempts to read the entire swap group of a physically swapped user **all at once**. A two-stage swap takes place for those users whose physical swap occurred because of migration from expanded storage. Primary working set is swapped in first, followed by the swap-in of secondary working set pages. The secondary working set usually consists of several swap sets.

   The swap-in of all the individual swap sets in a swap group or a secondary working set will take place concurrently, if these swap sets are located on distinct data sets, devices and paths. The concurrent I/O operations reduces the total time taken for swap-in, and exploits the bandwidth of multiple paths.

CHARACTERIZING PAGING OPERATIONS

PAGING TYPE	PAGES/ IO REQ.	PAGE DATA SET TYPE
PAGE-IN (FAULT)	1	LOCAL
STEAL (PAGE-OUT)	1-10	LOCAL
VIO	1-10	LOCAL
SWAP-OUT/IN, MIGRATED PAGE-OUTS, SWAP TRIM, MIGRATED SECONDARY WORKING SET	1-30	LOCAL
SWAP-OUT/IN, MIGRATED PRIMARY WORKING SET	1-12	SWAP
PLPA	1	PLPA
COMMON	1-10	COMMON

Figure 1. PAGING TYPES. (MVS)

Quantitative characterization of the various ASM paging operations is summarized in Figure 1. Page faults usually result in a single page transferred from DASD to real storage. Page-outs usually cause multiple (up to 30) pages transferred to local page data sets in a single I/O operation.

Swapping may occur to local or swap data sets. Swapping to swap data sets occurs in swap sets which may contain up to 12 pages. Since the use of swap data sets is usually inefficient in 3090 environments, the use of swap data sets will not be discussed in any detail. Swapping to local page data sets occurs in swap sets containing up to 30 pages. Local page data sets are not preallocated into swap sets since demand paging also occurs to these data sets, but the contiguous slot allocation algorithm attempts to place pages to be **swapped** into contiguous slots.

Paging from pageable link pack area (PLPA) and from/to COMMON page data sets is not discussed in this paper, since most of what can be said about demand paging considerations from LOCAL page data sets is directly applicable to PLPA and COMMMON page data sets.

The system interactive response time is directly influenced by the page-in and swap-in response times; page-out and swap-out response times do not directly impact system response times.

A PAGING CONFIGURATION

SWAPPING AND PAGING TO ALL LOCAL PAGE DATA SETS

In an expanded storage environment migration swaps go to local page data sets only. Hence in this environment usually only the use of all local page data sets make sense. These data sets can block up to 30 pages per I/O when used for swapping. The local data sets also handle the demand paging.

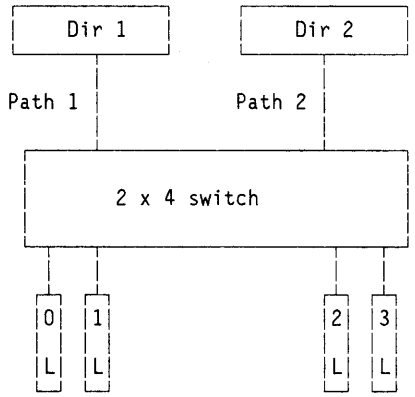

Figure 2. ALL LOCAL PAGING PATHS

Figure 2 shows all local paging paths, with four local paging actuators on two paths, with all actuators doing both paging and swapping. Assume that swapping occurs with 30 pages per I/O, page-outs with five pages per I/O and page-ins with one page per I/O.

Assume a swap to demand paging ratio of 4:1 with a swap load of 100 pages per second and a demand paging load of 25 pages per second per path.

		Page-in	Page-out	Swap
Blocking factor	=	1.0	5.0	30.0
Paging rate per actuator	=	6.25	6.25	50.0
Total path paging rate	=	125		
Path utilization	=	25.0 percent		
Actuator utilization	=	26.8 percent		
Actuator response time ms	=	28.0	33.5	76.5

Figure 3. LOCAL PAGING DEVICES WITH DEMAND AND SWAP PAGING

Figure 3 presents modelling results for all local page data sets handling both paging and swapping traffic. Observe that page-in response time is below 30 ms, which is my "rule of thumb" for acceptable response time. This rule of thumb was established pragmatically, it showed good overall response times, and did not result in excessive paging delays. Note the following advantages for the "all local" configuration.

1. ASM load balancing selects the local page data set with performance that is better than average among the set of local page data sets. Thus, local paging data sets on non-dedicated actuators or heavily loaded paths encounter lower paging loads. The automatic load balancing therefore corrects some performance problems dynamically. This capability exists only for local page data sets.

2. Migration paging from expanded storage is largely directed to local page data sets. If swap data sets are defined, only primary working sets are migrated to them. Thus, in an expanded storage environment the use of swap data sets is STRONGLY discouraged, because they tend to be underutilized.

UTILIZATION LIMITS FOR LOCAL PAGE DATA SETS

Modeling calculations have been used to establish device use limits (i.e., conditions under which the device utilizations and response times are reasonable and the queues occurring are not excessive).

Somewhat arbitrarily these limits were defined in such a way that paging path and device utilizations were kept below 35-40 percent. Experience shows that these are reasonable guidelines. Since the guidelines are somewhat arbitrary, an installation can load its devices more than the guidelines indicate, if it is willing to tolerate worse response times.

Device use limit tables for 3380 local paging devices are built with these guidelines. Three separate cases are considered:

- Dedicated demand paging paths (i.e., no swapping)
- Dedicated paging paths (with swapping)
- Nondedicated paging paths

LIMITS ON DEDICATED DEMAND PAGING PATHS

Number of actuators per path	4
Paging rate per actuator	< 25
Response time ms	< 30

Figure 4. LIMITS ON DEDICATED DEMAND PAGING PATHS

Figure 4 contains guidelines for dedicated demand paging paths. In such an environment it is assumed that swapping does not go to these paths, either because ASM swapping does not exist or it is minimal.

The guideline states that the maximum paging load for a 3380 paging actuator in a dedicated demand paging path should be 25 pages per second. This would result probably in a response time which is better than 30 ms. There should be at most four such demand paging actuators per path.

LIMITS ON DEDICATED PAGING PATHS (WITH SWAPPING)

Number of actuators per path	2
Swap to demand page ratio	>4:1
Paging rate per path	<125
Paging rate per actuator	< 63
Demand paging response time ms	< 30

Figure 5. LIMITS ON DEDICATED PAGING PATHS (WITH SWAPPING)

Figure 5 contains limits for the case of dedicated all-local paging paths that have both paging and swapping.

The essence of the guideline is that a local page actuator is required for:

- every 100 swap pages per second; and
- every 25 demand pages per second.

Hence, assuming a swap to paging ratio of greater than 4:1, two local paging data sets on a path can each sustain overall paging rates of up to 63 (since 2 times 63 equals 126) pages per second.

The path and actuator utilizations should be kept below 35-40 percent, so that the demand paging response time can be kept below 30 ms.

NONDEDICATED PAGING PATHS

Paging type on path	Demand only	Page and swap
Number of PAGING actuators per path	< 4	1
Number of actuators per path	4	4
Paging rate per paging actuator	< 25	< 63
Demand paging response time ms	< 30	< 30

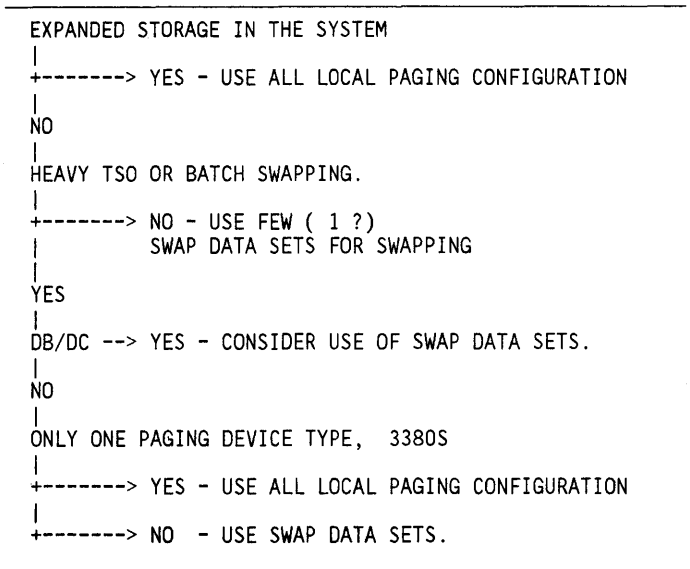
Figure 6. LIMITS ON PATH WITH DATA AND PAGING

Figure 6 summarizes some general rules for the case when (nonpaging) data sets containing data are commingled on the same path with local page data sets. The guidelines basically repeat the guidelines presented earlier. In general, this is a cost-effective solution, if the rules (on the maximum paging rates and number of paging actuators per path, and path utilization) are followed. Only one local page data set **doing swapping** (TSO environment) is allowed per path, but up to 4 demand paging data sets (DB/DC environment) are allowed. In order to limit the impact of mixing paging and data both, it is wise to limit the **overall** path utilization to a value below 35 percent.

For good performance one should place AT MOST two actuators that may service swaps into a string-switched complex of two paths.

CONFIGURING A SYSTEM

GUIDANCE FOR PAGING CONFIGURATION MIX



EXPANDED STORAGE IN THE SYSTEM
YES - USE ALL LOCAL PAGING CONFIGURATION
NO
HEAVY TSO OR BATCH SWAPPING.
NO - USE FEW (1 ?)
SWAP DATA SETS FOR SWAPPING
YES
DB/DC --> YES - CONSIDER USE OF SWAP DATA SETS.
NO
ONLY ONE PAGING DEVICE TYPE, 3380S
YES - USE ALL LOCAL PAGING CONFIGURATION
NO - USE SWAP DATA SETS.

Figure 7. DETERMINING PAGING CONFIGURATION MIX.

Usually the first question raised in configuring a system is whether swap data sets should be used. The easy and general answer is "NO" for 3090 environments with expanded storage. Figure 7 contains a guide in flowchart form with more detailed specific guidance on whether swap data sets should be used or not.

If there is expanded storage in the system, the use of swap data sets makes very little sense.

If there is no expanded storage in the system, and there is a swapping environment together with the presence of DB/DC, which is sensitive to demand paging, swap data set use should be considered.

If only one paging device type is used (especially 3380s) "all local" page data sets should be used most of the time.

In non-TSO environments a few (probably only one) swap data sets could be used to accommodate an occasional burst of heavy batch swapping and to avoid interference on the demand paging actuators.

PAGING SPACE CONSIDERATIONS

An important issue is the size of local page data sets. MVS currently (MVS/SP Release 2.1.3) limits the size of a 3380 page data set to 65400 slots. (That is about 250 megabytes). The sum of all local page data set space allocated should be at least **twice** as high in a 3090 environment as the available processor storage. Thus, if a 3090 has 128 MB of central and 256 MB of expanded storage for a total 384 MB of processor storage, then there should be at least 768 MB of paging space, (i.e., one can just about manage with three actuators). This rule of thumb ignores actual paging rates.

If any actual paging DOES occur, local paging actuators will be used more efficiently, because the contiguous slot allocation algorithm is used, if the allocated space on an actuator exceeds the space used by a factor of more than about four. Hence, in the above example, one should have at least six paging actuators allocated to the maximum extent permitted. In fact, I would modify this by saying that one needs about eight paging actuators. (The number is inflated to be on the safe side. In a knowledgeable installation the excessive allocation may not be required). In other words, there should be one 3380 local paging data set of 65400 slots on each of eight paths.

However, in most cases the actual paging load will be insignificant (i.e., a total of around 100 pages per second). Thus, the use of eight very lightly used dedicated actuators is not very cost-effective from the installation's point of view.

Thus, my new recommendation is to consider **the use of nondedicated paging actuators** on nondedicated paging paths. A page data set uses about half of a 3380 model D actuator, and less than one quarter of a model E; so perhaps model E use should be considered. The only concern is to keep both the actuator and path utilizations below 30 percent. This says that the use of expanded storage frees up (at least partially) the previously dedicated paging actuators for other use.

-Allocate 65400 slots per local page data set

-Use at least eight local page data sets

-Use nondedicated paging devices

Figure 8. PAGING SPACE CONSIDERATIONS

Figure 8 summarizes the considerations just discussed.

A CONFIGURING EXAMPLE USING PAGING RATES

-Swap group size = 90 (storage isolated)

-Swap paging rate, SR = 400 pg/s

-Demand paging rate DR = 100 pg/s

Figure 9. PAGING RATE DESCRIPTION

In this section page/swap configuration alternatives are examined, assuming that significant paging loads are encountered. Figure 9 contains the description of the paging workload. Assume a total swap paging rate of 400 pages per second, and a demand paging rate of 100 pages per second, with a swap group size of 90 pages.

CONFIGURING FOR THE PAGING LOAD

The first step in configuring for swapping is to establish the number of paths required for good swap-in response times. A high level of parallelism is required for good swap-in response time. In order to obtain this, we divide the swap group size, SG, of 90 with the swap set size, SS of 30.

The minimum level of parallelism can be determined by dividing the swap group size, SG, with the swap sets size of 30. The minimum level of parallelism should be

SG / SS = 90 / 30 = 3.

The conclusion may be reached that from a concurrency viewpoint at least three independent paths are required for an all local paging environment.

The next step is to consider the number of 3380 actuators required for swap paging. The guideline says a potentially swapping actuator is capable of transferring up to SP=100 pages per second. Thus, the number of 3380 local page data sets required for swapping, NS, is four,

NS >= SR / SP = 400 / 100 = 4

i.e., at least four local paging actuators are required to accommodate the swap paging requirements.

The next step is to consider the number of 3380 actuators required for demand paging. The demand paging rate required is DR = 100 pages per second. A 3380 demand paging actuator can sustain a demand paging rate of DL = 25 pages per second according to the guidelines. Hence the number of local page data sets required for demand paging, ND, is four, because:

ND >= DR / DL = 100 / 25 = 4

The number of 3380 local demand paging actuators is additional to the number established by the swap paging requirements.

Thus, the total number of local paging actuators required is

NS + ND = 4 + 4 = 8

CONFIGURATION ALTERNATIVES

Now the configuration alternatives can be summarized. In the notation below "L" represents a local paging actuator, and "D" a non-paging actuator with data, such as TSO work packs. Paths are separated by commas.

1. All local paging on dedicated paths. The calculation showed the requirement for at least four demand paging and four swap paging actuators, for a total of eight local paging actuators on at least four paths. This exceeds the minimum parallelism requirement of three. Hence the configuration with dedicated paging paths is

   LL, LL, LL, LL

2. All local paging using non-dedicated paging paths. The calculation showed the requirement for at least four demand paging and four swap paging actuators, for a total of eight local paging actuators. We place them on eight non-dedicated paging paths. This exceeds the minimum parallelism requirement of three. Hence the configuration is

   LDDD, LDDD, LDDD, LDDD, LDDD, LDDD, LDDD, LDDD

   It is likely that this solution provides the better paging response times.

SUMMARY OF METHOD

A paging configuration design method was presented, assuming that the configuration is to be organized on the basis of paging load rather than space. The first step is to determine the paging load to be sustained. The next step is to determine the parallelism required, and the final step is to determine the number of paging actuators required to accommodate both swapping and paging.

Having determined the number of paging actuators and the required parallelism, the paging actuators can be configured on paths to meet the installation objectives regarding isolation of paging paths and/or isolation of data paths.

A CASE STUDY

In this chapter a case study of a 3090 installation is presented. The objective of the study is to describe some of the paging considerations in an environment with expanded storage. The installation had a 128Mb IBM 3090/400 configured with 128 MB expanded storage. There were a maximum of 430 TSO users on the system in the measurement period. An additional 40 batch initiators and 80 started tasks were also running. CPU utilization was about 93 percent.

THE PAGING ACTIVITY REPORT

Paging activity report

Rate of page movement to ES =417

Main Storage Paging Rates

	PAGE IN		PAGE OUT		Migration rate = 64			
	SWAP	NON SWAP	SWAP	NON SWAP	High UIC		Migr Age	
					Min	Avg	Min	Avg
NON-VIO	49	32	24	0.3	34	93	349	370

Figure 10. AN EXAMPLE OF PAGING ACTIVITY REPORT

An example of a RMF Monitor I Paging Activity report page I is given in Figure 10.

Observations.

- Expanded storage absorbs most of the potential paging i.e., 417 pages per second (out), and we may assume as a first approximation that a similar amount (in). (The assumption can be justified by saying that what goes out, tends to come in.) Contrast this with 49+32 total page-ins from auxiliary storage. The "hit ratio" on expanded storage is about 417/(49+32+417) = 84 percent.

- There is no shortage of central or expanded storage; since the UIC is greater than 30 seconds, and migration age is greater than 100 seconds. (Migration age is an indicator representing the life of pages on expanded storage in seconds before they are migrated. This number is an indicator of storage pressures on expanded storage).

- Swap-in from auxiliary storage (49 pages per second) is higher than swap-out to auxiliary storage (24). What? What comes in, must go out first. (The problem is that migrated swap-out pages are not fully counted in the swap-out category, only the migrated primary working set is counted).

- The page-in rate from auxiliary storage (32) appears relatively high in comparison with the swap-in rate (49). This question is worth addressing further. The immediate hypothesis is that there is no (or not enough) storage isolation, which inflates the page trims, that result in page-ins. The Installation Performance Specification (not shown here) confirms that there is NO storage isolation on the system.

- There is almost no page-out activity to auxiliary storage. (It goes to expanded storage first).

- The maximum paging activity can be roughly calculated. The expanded storage migration rate of 64 pages per second includes secondary working set swap-outs. Assume that it DOES NOT include primary working set swap-outs (which are included in the swap-out report). Thus an upper bound on (ASM) paging is

  49 + 32 + 24 + 0.3 + 64 = 169 pages per second

  If the system did not use swap data sets, the page data set report would provide an absolute count.

THE SWAP PLACEMENT ACTIVITY REPORT

Swap placement activity

Note: numbers are rounded for space reasons

	Tot Dir	Aux Swap	Log Dir	ES Aux Tot	ES Tot	ES Eff	Log Eff	Migr fr E	L/E Eff	%
Trm. I/O wait rate	16.1	.23	15.7	.21	.46	2.7	2.5	13.1	.19	15.6	97
Tot.	19.9	.23	19.5	.23	.56	3.0	2.8	16.6	.26	19.4	97

Average pages per swap-out = 44, per swap-in =87

Figure 11. AN EXAMPLE OF SWAP PLACEMENT ACTIVITY REPORT

An example of a RMF Monitor I Paging Activity report page 2, the Swap Placement Activity report is given in Figure 11.

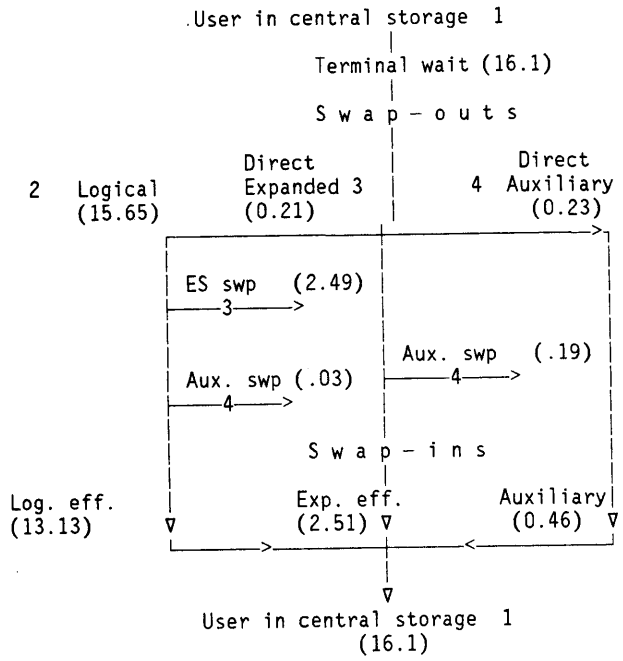


Figure 12. A representation of swap states

Figure 12 shows the various swap states in a state diagram. The user in central storage (1) enters terminal wait, therefore he is logically swapped (2), or direct swapped to expanded storage (3) or direct swapped to auxiliary storage (4). Both logical and expanded storage swaps can be converted into auxiliary storage swap-outs (4). Logical storage swap-out can also be converted into expanded storage swap-out (3). A user in any of the three swapped out states (2,3,4) ultimately reenters (swapped back in) into central storage (1).

The effectiveness of processor storage swap is indicated by the sum of the effectiveness of logical and expanded storage swaps.

Observations

- The terminal I/O wait rate is 16.1 per second, and auxiliary storage swap-in is only 0.46 per second, 2.8 percent of the total. Thus, auxiliary storage swap activity is not very heavy. The average swap-in size is the swap-in page rate of 49 divided by the aux. swap-in rate: of 0.56, which comes out to be 87 pages per second. (The average swap-in size is correctly reported on the report, but the average swap-out size is not).
- Non-swap page-ins represent an upper limit to swap trim. Thus, swap trim must be smaller than 32 pages per second. The overall swap rate is 20 transactions per second. Thus, if all paging came from swap trim, it would be (32 / 20 = 1.6), i.e., 1.6 page-ins per transaction.

RMF MONITOR I PAGE/SWAP DATA SET ACTIVITY REPORT

Interval = 15 (minutes)

Pag Spc Typ	Dev Num	Dev typ	% in Use	Pag XFR Tim	Rate I/O Req	Pag XFR Rate	Blk Fac tor	Allc Slts Thousands	Slts Used
LCL	1AA	3380	15	7	5.33	20.9	3.9	45	20
LCL	717	3380	28	17	4.57	16.5	3.6	45	20
(6 local data sets)									
Total						116			
					Serv Time				
SWP	627	3380	1.8	27	0.74				
(6 swap data sets)									

Figure 13. PAGE (SWAP) DATA SET USAGE REPORT FROM MONITOR I

Figure 13 shows extracts from the page and swap data set reports. The "I/O rate" and "blocking factors" columns do not appear on the report, the values in them were obtained by straightforward calculations[3].

Observations

- The use of the swap data sets is wasteful. Their utilization is very low, as expected in an expanded storage environment. The installation would gain by converting its swap data sets into local page data sets. Probably some of the twelve data sets could be used for other purposes.
- The two different local page data sets present very different measurements. Device 1AA has a reasonable average paging response time of about 30 ms, (3.9 times 7 milliseconds) device 717 has about double that

[3] Divide the reported page transfer count by the report interval duration to obtain the page transfer rate. Divide the reported page transfer count by the reported number of I/O requests to obtain the blocking factor.

amount. A further examination from the device and control unit reports is called for.

RMF MONITOR I DIRECT ACCESS DEVICE ACTIVITY REPORT

Dev CU Num	% in Use	Act Rate	Ave Resp Time	Ave IOSQ Time	Ave Pend Time	Ave Disc Time	Ave Conn
1AA	14	5.3	28	0	0.5	20.4	6.9
(1AA is typical paging device)							
00B		51.2	23	2	0.8	15.5	5.0
717	26	4.6	57	0	1.1	48.4	6.5
(717 is a paging device)							
707	94	22.3	162	117	2.1	35.9	7.7
(707 is a nonpaging device)							
024		190.2	50	25	1.7	18.2	4.4

Figure 14. DIRECT ACCESS DEVICE ACTIVITY REPORT FROM MONITOR I

Figure 14 shows extracts from the device activity report. The Logical Control Unit, (LCU) 024 consisting of two actual control units has high I/O activity rate (190 I/Os per second), which causes the paging device 717 to encounter a rather high disconnect time. (Disconnect time is the sum of latency, 8.3 ms plus RPS miss, the latter caused by path contention, plus seek time. Seek time on paging devices is normally very low, of the order of 3-4 ms). Observe that even device 1AA has high disconnect time, which is not easy to explain. One clue is obtained from the page data set usage report. On each local data set 45000 slots are allocated and about 20000 used. That is insufficient for the contiguous slot allocation algorithm to work effectively. As stated earlier, the number of available slots should be at least four times as large as the number of slots used. The allocation size should be increased to 64000 slots, and more local page data sets should be used. The excess latency and seek times would then be reduced.

CORRECTIVE ACTIONS FOR PAGING PROBLEMS

I want to emphasize that in a modern system environment paging problems can and should be avoided. When paging problems do occur, then they usually manifest themselves in slow TSO or DB/DC response times. Correcting these problems usually results in improved response time. Designing for response time is very important, since it results in better people productivity, which reduces people cost.

Paging problems can be reduced by providing additional hardware so as to reduce paging or make it faster or by tuning actions. These solutions are listed in the order they should be pursued.

The tuning solutions usually result in a better performing paging subsystem by reducing paging altogether, and as a next step, enhancing and increasing swapping and, simultaneously, reducing demand paging.

The solutions (below), have been presented before, here cognizance is taken of the presence of expanded storage.

1. REDUCE ALL KINDS OF PAGING.

   Problem: Heavy demand and swap paging, slow response times, slow page fault resolution.

   Solution: Increased processor storage (hardware).

   When processor storage is increased, paging rates (all kinds) are reduced. The effect is to decrease:

   - CPU cycles associated with paging.
   - The required number of paging devices.
   - The paging load carried by channels.

   When the processor storage used is at its limit, then (and only then) it is worthwhile considering other solutions.

2. CONTROL TSO DEMAND PAGING

   Problem: Heavy demand paging, slow TSO response times, slow page fault resolution.

   Solution: Introduce storage isolation for trivial TSO address spaces (tuning action).

   This can be done by using the PWSS parameter for trivial TSO transactions (i.e., for the trivial TSO performance group period). The effect is that demand page load is decreased, but swap load is increased. A further effect in an expanded storage environment is that the page-outs to auxiliary storage use the contiguous slot allocation algorithm, using the devices more effectively.

   Because of storage isolation the short term central storage occupancy of a TSO address space may increase, but the overall central storage occupancy (the frame-second product) decreases because of the shorter time spent in central storage waiting for page faults.

3. CONTROL DB/DC, JES, STARTED TASK DEMAND PAGING

   Problem: Heavy demand paging, slow DB/DC response times, hesitating printers, slow page fault resolution.

   Solution: Introduce storage isolation for these address spaces (tuning action).

   This can be done by using the storage isolation parameters PWSS and/or PGRT for the response time sensitive, usually nonswappable address spaces, such as IMS control region or message processing regions, CICS address spaces, or JES.

   The effect is that for the storage isolated nonswappable address spaces the demand page wait states are reduced, thus transaction response time improves. The processor storage occupancy of these address spaces becomes much more stable even though it may become larger. Batch and TSO swap load is increased.

4. REDUCE SWAP-IN DELAYS

   Problem: Slow TSO response times, large swap-in delays

   Solution: Provide maximum parallelism for swapping (tuning action).

   This means that the swap paging load is distributed to as many, non-dedicated paths as there are swapping actuators. In particular, use an all-local paging configuration, placing one or at most two such actuators per string-switched path complex. Result

is that more paths are used concurrently, and swap delays are reduced. As swapping takes place faster, the address space takes up central storage for a shorter period of time, and this in turn reduces demand paging. Central storage occupancy is measured in frame-seconds, and the shorter the period the address space spends in waiting for swap-in, (or page faults), the less real storage is occupied by that address space. As an example, an address space with 72 frames and a response time of 0.3 seconds occupies 72 x 0.3 = 21.6 frame-seconds. The transaction with a one second response time occupies more than three times as much. The smaller this figure is, the smaller impact it represents to the system.

Swap traffic may cause momentary delays for non-swap I/O on the non-dedicated paths, usually this is not significant however.

In an expanded storage environment (with swapping to expanded storage) generally do NOT use swap data sets, since only the primary working sets migrate to swap data sets.

5. CONTROL OVERALL DEMAND PAGING RATE

Problem: Slow TSO response times, large page-in delays

Solution: Change the IEAOPTXX PARMLIB member so that the SRM decides to swap-out long running TSO transactions and batch whenever page fault rate exceeds a threshold (RCCPTRT).

The result is reduced multiprogramming level, increased swapping and reduced paging. TSO response time improves.

6. CONTROL LOGICAL SWAPPING

Problem: Slow TSO response times, large page-in delays

Solution: Decrease the maximum system think time, LSCTMTE (tuning action) in an environment WITHOUT expanded storage.

When the "system think time" parameter is reduced to a small number, say, 1-5 seconds, from the MVS default of 30 seconds, only those users are logically swapped (in central storage only), who interact with the system very fast. As a result, the central storage occupancy of logically swapped users is reduced, the central storage available for frames containing unreferenced pages with steadily increasing UIC values is increased, and demand paging is reduced. Physical swapping will increase at the same time.

The rationale is that slow users do not deserve to occupy central storage when fast users are deprived. Do NOT use this tool in a system with expanded storage.

7. SPEED UP PAGING

Problem: Heavy demand and/or swap paging, slow response times, slow page fault resolution.

Solution: Enrich the paging subsystem (hardware). All the tuning actions recommended have been tried, the processor storage is at its maximum, and paging delays are still significant. Thus, more and faster paging devices should installed. If swapping is the problem, more 3380 actuators should be installed on more paths. If paging is the problem, replace 3380s with larger 3880-21s, (assuming no more processor storage can be obtained). (This problem probably occurs in non-3090 environments only).

CONCLUSIONS

The easiest way to solve paging problems is by obtaining more processor storage.

The most flexible paging configuration is an all local paging configuration.

For local page data sets the maximum local page data set size, 65400 should be allocated.

For good ASM swap response multiple swap paths are required. Thus, multiple local paging 3380 actuators distributed on non-dedicated paths should be used if possible.

In an expanded storage environment, ONLY ALL-LOCAL paging configurations should be used.

In an expanded storage environment, the use of nondedicated paging devices should be considered.

ACKNOWLEDGEMENTS

I want to thank my colleague, Mr. B. Pierce for reviewing this paper.

ABSTRACT

The IBM 3090 processor series introduced a new architectural feature called Expanded storage. Prior studies at Bell Communications Research determined the performance of the 3090 model 200 relative to a 3084QX in Single Image mode, and of the 3090-200 relative to a 3090-400 in Single Image mode. These tests were conducted using MVS/SP 2.1 (MVS/XA) as the primary control program (both MVS 2.1.3 and 2.1.7 were used). The environments tested included a dedicated online IMS system (both IMS 1.3 and 2.1 were used) as well as a combined development and production scientific workload. This report documents our findings on the use of Expanded storage in a dedicated IMS environment, both as a paging device and as a Virtual Fetch device.

Significant performance improvements are seen with Virtual Fetch when Expanded storage is used. In the lightly loaded case, Schedule to First DL/I time is reduced 82% by using Expanded storage. In the heavily loaded case, Schedule to First DL/I time is reduced by 66% by using Expanded storage, and mean program execution time is reduced by 25.5%.

Expanded storage is an extremely fast paging device. However, it can be overcommitted. In one test designed only to produce demand paging, severe thrashing occurred as the ES rate approached 1800 pages per second.

1. Background

With the announcement of the model 200, IBM introduced the 3090 processor series, consisting of high capacity, single and multiple CPU general purpose computer systems. The IBM 3090 series introduced a new memory architecture option known as Expanded storage. With this option, two random access memories are present in the hardware configuration: the primary storage, called the Central storage (previously referred to by IBM as the Real storage), and a secondary storage, called the Expanded storage, used only for paging and swapping operations. The purpose of Expanded storage is to reduce the paging and swapping load to the channel attached Paging devices.

Two types of tests were conducted to determine the performance implications of using Expanded storage on a dedicated IMS environment. The first test is the use of IMS Virtual Fetch (potentially high VIO paging load) and the second test is the use of IMS Preload (potentially high demand paging load). Both of these tests are compared to the baseline case of IMS using Real Fetch.

The use of Expanded storage is explored here. The size of the Central storage (Real storage) is fixed at 64 Mbyte for the 3090-200 and this size was not an option.[1]

1.1 What is Expanded Storage?

Expanded storage is an architectural extension of the 3090 series processors. It is available as an optional feature in 64 Megabyte increments up to 256 Megabytes[2] (512 Mb on the 3090 model 400) in addition to the required 64 Megabytes (128 Mb on the 3090 model 400) of Central storage. Expanded storage is a high speed, reduced function memory designed specifically for paging and swapping operations to and from Central storage. It is called a *reduced function memory* because it *cannot* be used for program execution (active pages *must* be resident in Central storage), nor can it be used for I/O Operations (channel data paths are only connected to the Central storage). Transfers between Expanded storage and Central storage are performed in 4096 byte units (pages). Space in Expanded storage is managed with an approximation of the Least Recently Used (LRU) algorithm, the same as that used for Central storage. Therefore, though some paging occurs based on internal algorithms, almost no paging-related I/O occurs to the channel attached paging devices until Expanded storage is fully committed. Expanded storage is supported by MVS/SP 2.1.3 and is transparent to all application programs. Figure 1 depicts a high level view of the Expanded storage architecture.

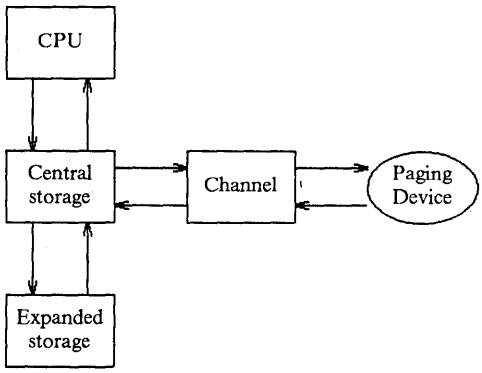

Figure 1

One might ask why Expanded storage was introduced, rather than just adding more Central storage. Even though the real storage cost per Megabyte declines, the complexity of *fully connecting* it to a system places limits on the price-performance improvement. Storage must be accessible to the I/O subsystem, as well as to all connected processors. When connected

1. The new 3090E series is available with either 64 or 128 Megabytes of Central storage.
2. Note that these numbers reflect the February 11, 1986 announcement by IBM; less was available at the time of testing.

*** This author is currently on a sabbatical leave from the College of Staten Island, a unit of the City University of New York. This work was conceived and performed while at Bell Communications Research, Inc., Piscataway, New Jersey.

to processors, the data flows through expensive cache buffers, so that instructions and data are passed at cycle speeds to the processors. As the workload continues to grow, so does the need for real storage. Increasingly high levels of multiprogramming make the storage reference patterns more random; thus, more circuitry must be devoted to cache to maintain acceptably high hit ratios. If continued improvements of fully connected storage approach a complexity barrier with respect to circuitry, then Expanded storage is a *partially connected* solution.

2. Terminology

To understand fully the performance effects of Expanded storage, some key definitions of measurement terms are in order:

- *ES Rate* (pages/second) - The rate of page movement from Central storage to Expanded storage.
- *Migration Rate* (pages/second) - The rate of page movement from Expanded storage to the Channel-connected paging devices.[3]
- *Migration Age* (time in seconds) - The amount of time a page resides in Expanded storage before migrating to the Channel attached paging device.
- *Criteria Age* (time in seconds) - A user specified parameter used to determine if a page being removed from Central storage is to be sent directly to the Channel attached paging devices rather than being sent to Expanded storage.[4]
- *Page In* - The movement of a page from the channel attached paging devices to the Central storage.
- *Page Out* - The movement of a page from the Central storage to the channel attached paging devices.

3. Description of IMS Workload - Small Memory Load

There are two primary variables in this study, the use of Virtual Memory by the online IMS system and the resulting load on the paging subsystem. The use of Virtual Memory by MVS, VTAM, etc., remained constant throughout the study and is not described in this report.

The online application used in these tests was run under the control of MVS/SP 2.1.3 and IMS 1.3. The application consisted of 150 transactions and programs run at volumes high enough to have the CPU utilization between 75% and 90%. The program size ranged from 19 Kbytes to 455.6 Kbytes. Since all programs were not run with equal frequency, the average size of a program fetched for execution was 54 Kbytes. The total size of the 150 programs executed during the tests was 12,212 Kbytes. For the application programs to execute correctly, 1,496 Kbytes of subroutines must be preloaded into each processing region. Accounting for the various IMS modules that must be present in the Dependent Regions, the maximum size of a dependent region is 2,028 Kbytes for the Real Fetch and Virtual Fetch tests.

The total Virtual storage requirements for the IMS system are:

- Control Region - 2,124 Kbytes
- DL/I Address Space - 7,440 Kbytes
- DBRC - 500 Kbytes
- Dependent Regions - 28 regions at 2,028 Kbytes each = 56,784 Kbytes.

This IMS system, run on an IBM 3090-200 with 64 Mbyte Central storage and no Expanded storage, produced almost no paging activity (less than 0.1 pages/sec.) over all volumes tested.

3.1 Real Fetch

The baseline set of tests was the IMS application described above, run on 64 Mbytes of Central storage and no Expanded storage. Five copies of the program load library were alternated among the 28 message processing regions to minimize contention. Schedule to First DL/I time averaged 77.76 milliseconds and there was no paging to the channel attached paging devices.

3.2 Virtual Fetch Description

Virtual Fetch is a feature of the MVS contents supervision function. IMS releases 1.2 and above have been written to exploit this MVS feature at the option of the particular installation. Virtual Fetch was written to address the problems associated with MVS fetch and IMS Preload. Virtual Fetch executes in an independent address space, thereby providing Virtual Fetch services to all other requesting address spaces. Load modules that are specified by the installation are loaded and maintained by Virtual Fetch in VIO datasets created by Virtual Fetch initialization. Modules managed by Virtual Fetch may be invoked by *any address space* with Virtual Fetch requests. When an application requests Virtual Fetch services, Virtual Fetch pages the specified module into the requester's address space and passes control to it. Thus, by using both VIO and Cross Memory Services in MVS, Virtual Fetch provides yet another mechanism for managing IMS online application programs.

IMS Dependent Regions use Virtual Fetch services when the installation provides an IMS Parmlib member with the names of the particular programs to be processed by Virtual Fetch. Each dependent region can have a different list of Virtual Fetch programs. In our tests, each of the 28 dependent regions were given a list of all 150 programs that make up the application. Therefore, Virtual Fetch managed all 150 programs totaling 12,212 Kbytes in the VIO dataset.

3.3 Virtual Fetch Analysis

Prior investigations conducted at Bell Communications Research have assessed the relative performance of the different program load methods. The IMS trace facility (DCMON) provides a measurement called Schedule to First DL/I Call time.[5] This measurement reports the time between the dependent region being told which application program to execute and the application program making its first DL/I Call (usually a call to receive the message text). One function that is performed in this interval is locating and placing into memory the required application program. We use Schedule to First DL/I as an indirect measure of the efficiency of the various program management techniques. Measurements on previous processors show that Real Fetch is the slowest method, Virtual Fetch takes roughly half the time of Real Fetch, and Preload takes roughly half the time of Virtual Fetch.

Table 2 illustrates the results of our Virtual Fetch experiments with Expanded storage. The value for Schedule to First DL/I Call using Virtual Fetch on the 3090/200 *without* any Expanded storage was 47.84 milliseconds; this is 61.5% of the corresponding value (77.76 msec) found for Schedule to First DL/I Call using Real Fetch on the 3090-200. Note, though, that the paging rate had increased from 0 to 337 pages per second. When 64 Mb of Expanded storage was added, the value of Schedule to First DL/I was reduced to 8.72 msec, a reduction of 89% over Real Fetch, and a reduction of 82% over Virtual Fetch without Expanded storage. Note that because Expanded storage was *not full*, almost no I/O's were performed to the paging subsystem. Also note the negligible effect on both Schedule to First DL/I time and on the paging rate when Expanded storage was increased from 64 Mb to 128 Mb. This data is presented graphically in Figure 3.

Effects of Virtual Fetch on Program Load Time

Environment	Expanded Storage (size)	Schedule to First DL/I (msec)	Paging Rate IN + OUT (per second)
Real Fetch	0 Mb	77.76	0.11
Virtual Fetch	0 Mb	47.84	337.08
Virtual Fetch	64 Mb	8.72	0.12
Virtual Fetch	128 Mb	8.97	0.18

Table 2

3. Since an address in Expanded storage cannot be used as the source or destination of an I/O operation, an intermediate move of the data is made to Central storage before the physical I/O operation is performed to the channel attached device.
4. See section "Controlling Expanded storage" for the use of this parameter.
5. See: S. Hoyt, "IMS/VS/MVS Performance and Tuning Guide, IBM Corp., G320-6004, April, 1986, for a complete definition.

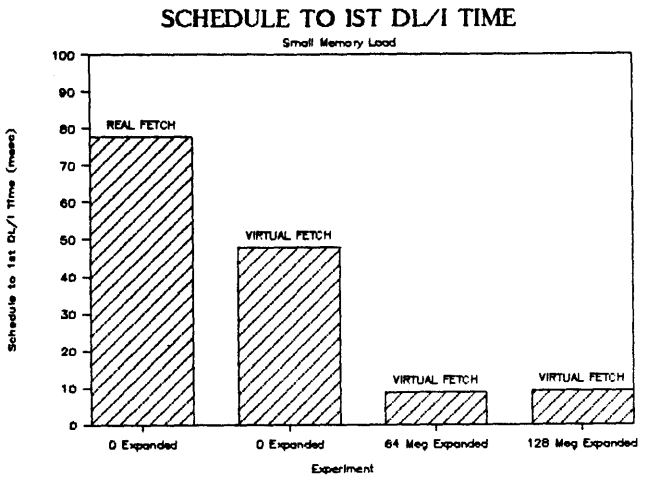

Figure 3

3.4 Summary - Small Memory Load

Virtual Fetch provides a performance improvement over Real Fetch. However, a considerable load is placed on the paging subsystem.

In this section, the functionality of Expanded storage in isolation was tested. The memory commitment and the paging subsystem were not excessively stressed. In the next section, we determine if the performance improvements gained through Expanded storage are maintained when the memory is overcommitted, and the paging subsystem is stressed.

4. Description of IMS Workload - Large Memory Load

For the IMS Preload experiments, we would have liked to keep the workload constant. However, if all 150 programs were to be preloaded, this would have required an MVS private area greater than 12 Mbytes. Instead, we preloaded *60* programs and used Real Fetch on the remaining *90* programs, and maintained the same hourly volumes as the previous experiments. As before, the program size ranged from 19 Kbytes to 455.6 Kbytes. The total virtual memory required for each dependent region is 6964 Kbytes, allocated as follows: 4884.8 Kbytes for preloaded programs, 1496 Kbytes for preloaded subroutines, 455.6 Kbytes for fetched modules, and the remainder for the region controller. Using 28 dependent regions, the total Virtual memory requirement for the message regions is 194,992 Kbytes (28 * 6964) or 190.422 Mbytes. To calculate the total Virtual memory requirement, we add *2124* Kbytes for the IMS Control Region, *7440* Kbytes for the DL/I Address Space, and *500* Kbytes for the DBRC Address Space. This yields a total Virtual memory requirement of *205,056* Kbytes, or *200.25* Mbytes. To put this in perspective, our moderately loaded systems' average Virtual memory requirement is 140 Mbytes.

4.1 IMS Preload Description

IMS Preload operates in a different fashion than either Real Fetch or Virtual Fetch. Rather than loading a module at each program scheduling, IMS Preload loads installation-specified modules into the dependent region private area at the time of initialization of the dependent region. Once a module has been preloaded, its starting address is saved in a table; later requests for the scheduling of an IMS Preload-managed module results in a table lookup and a direct branch to the module's virtual storage address.

Unless a program is reasonably active throughout the life of the dependent region, its pages will age and will most likely be replaced or paged-out, depending on whether they have been updated. When IMS branches to one of these "aged" modules, a page-fault occurs, generating a request to page in the required page frame; this causes a delay in processing owing to page fault resolution. In addition, each reference to a page of the program that has been paged-out to "auxiliary" storage causes a page fault. This is known as *serial page faulting*, and usually causes an increase in both Schedule to First DL/I time and program elapsed time. Finally, significant stress is placed on the paging subsystem, eventually affecting the entire MVS system.

4.2 Analysis of Program Load Time

The first set of experiments was designed to determine the amount of relief Expanded storage provides to the channel attached paging subsystem. Here, identical workloads were executed with and without Expanded storage to compare directly the effects on the paging subsystem. To increase the load on the paging subsystem, 60 programs were still preloaded into each processing region, and the remaining 90 programs were placed under the control of Virtual Fetch. This results in the same virtual memory commitment (200.25 Mbytes) as described above. The paging subsystem in these experiments consisted of two 3880-model 21 paging controllers (each with 32 Mbytes of cache), and four 3350s containing local page datasets. The baseline case was run with no Expanded storage. The second case was run with 64 Mbytes of Expanded storage.

Without Expanded storage, the total paging load was 370 pages per second, 222 pages/second for VIO, 73 pages/second for Page In, and 75 Pages/second for Page Out. Schedule to First DL/I Time for Preloaded programs averaged 89.04 milliseconds, while Schedule to First DL/I Time for the programs under the control of Virtual Fetch was 63.36 milliseconds. This is counter to previous findings.

Demand paging and VIO were not segregated in the configuration. Both types of paging activity competed for device service and space in the cache controller. In our case, a Virtual Fetched module is referenced 18.67 times more frequently than a preloaded module[6]. We conclude the Schedule to First DL/I time is shorter for Virtual Fetch because of a higher read hit ratio in the cached paging controller.

With Expanded storage, the total paging load was 25 pages per second, 18 pages/second for VIO, 3 pages/second for Page In, and 4 pages/second for Migrate Out. Schedule to First DL/I Time for the preloaded programs was 9.11 milliseconds and for Virtual Fetch it was 21.70 milliseconds. By relieving the congestion on the channel attached paging subsystem, the relative performance of preload versus Virtual Fetch has been restored (i.e. preload is 58% of Virtual Fetch). Though both sets of transactions benefit greatly from the addition of Expanded storage, the Preloaded transactions experience a *90%* reduction in Schedule to First DL/I time, while the Virtual Fetch transactions see a *66%* reduction. These results are summarized in table 4 and figure 5 below.

Analysis of elapsed time without Expanded storage showed that the mean program execution time was 795.81 milliseconds; with Expanded storage, this was 592.12 milliseconds. This is a decrease of 25.5%. At the 90th percentile level, the program execution time 2.05 seconds without Expanded storage and 1.5 seconds with Expanded storage. This is a decrease of 26.8% indicating that all programs receive the same benefit from Expanded storage.

An additional experiment with real memory overcommitted had 60 programs preloaded into each region, and the remaining 90 programs under the control of Real Fetch. This experiment was designed to be compared with the Real Fetch and Virtual Fetch experiments of the previous section. This experiment was conducted on a 3090-200 with 64 Mbytes of Central storage and 64 Mbytes of Expanded storage. The channel attached paging subsystem was a 3880-21 with 32 Mbytes of cache and four 3350s with local paging datasets. Preloaded programs averaged 9.87 msec Schedule to First DL/I time while the program using Real Fetch averaged 84.77 msecs. Although the Central storage was overcommitted, the use of Expanded storage minimized the activity to the channel attached paging subsystem. The total load on the channel attached paging subsystem was 28 pages per second, 12 pages/second for page in and 16 pages/second for migrate out. When compared to the results of the previous section, Schedule to First DL/I Time increased 7 milliseconds (9%) for the programs under the control of Real Fetch. Preloaded programs in the stressed case were slightly slower (1.15 milliseconds) than the Virtual Fetched programs in the unstressed case with Expanded storage. Because of time constraints, this experiment was not repeated without Expanded storage.

Effects of Virtual Fetch vs. IMS Preload			
Environment	Expanded Storage	Schedule to First DL/I (msec) Preload	Fetch
Preload/Virtual Fetch	.0 Mb	89.04	63.36
Preload/Virtual Fetch	64 Mb	9.11	21.70
Preload/Real Fetch	64 Mb	9.87	84.77

Table 4

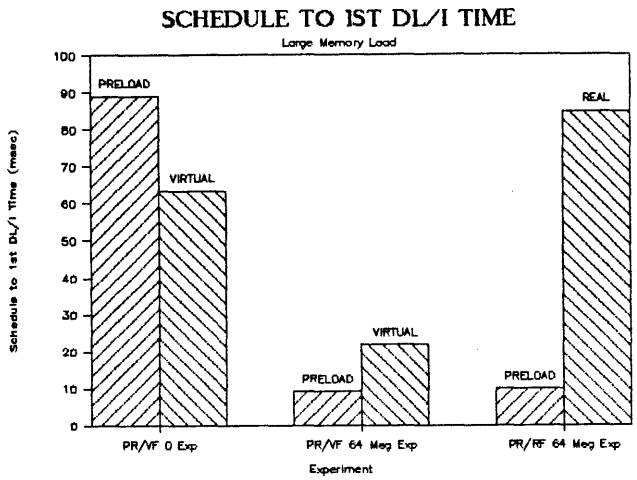

Figure 5

4.3 Analysis of Paging Subsystem

Expanded storage was designed to reduce the load on the channel attached paging subsystem. From the experiments conducted, the most direct comparisons can be made from the Preload-Virtual Fetch runs, with and without Expanded storage.

Without Expanded storage the total paging rate was 370 pages per second. With Expanded storage, the rate dropped to 21 pages per second. This is a reduction of 94.3%. VIO page in was reduced by 91.9%, demand page in was reduced by 95.9%, and demand page out was reduced by 100% (i.e page out was zero). See table 6.

Along with this reduction in paging rate, there are similar savings at the device level. The device activity rate (totaled for all devices in the paging subsystem) dropped from 92 operations per second to 22 operations per second when Expanded storage was added (72% reduction). Device response time dropped from 31 milliseconds to 3 milliseconds (93% reduction). Page transfer time dropped from 8 milliseconds to 1 milliseconds (87.5% reduction).

Although there were significant changes to the channel attached device activity, the activity in and out of Central storage remained the same (as one would expect). One measurement (activity from Expanded to Central storage) is not recorded. Therefore our conclusion can be inferred, not proved, from the data.

Without Expanded storage the demand page in rate was 73 pages per second and the demand page out rate was 75 pages per second, or nearly the same. With Expanded storage, the page in rate was 3 pages per second and the migrate out was 4 pages per second, again nearly the same. The 75 page out operations per second without Expanded storage went to zero with Expanded storage. However their movement out of Central storage is recorded in the ES Rate (movement from Central to Expanded). Accounting for the 4 pages per second that eventually migrate out to the DASD, we have a Central storage page out rate of 74 pages per second, nearly identical to the page out rate in the case without Expanded storage. Since in the case without Expanded storage, the in rate equaled the out rate, we assume these 74 pages per second are referenced within the migration age and are moved back to Central storage (the equivalent of an ES IN which does not exist as a recorded measurement).

Paging Subsystem Analysis				
		PRELOAD / REAL FETCH 64Mb Central / 64Mb Expanded	PRELOAD / VIRTUAL FETCH 64Mb Central / 0Mb Expanded	PRELOAD / VIRTUAL FETCH 64Mb Central / 64Mb Expanded
VIO Rate	(per sec.)	0	222	18
Page In Rate	(per sec.)	12.47	73	75
Page Out Rate	(per sec.)	0	75	0
ES Rate	(per sec.)	75	0	78
MIG. Rate	(per sec.)	16	0	4
High UIC	(seconds)	34	46	50
Dev. Activity Rate	(per sec.)	14	92	22
Response Time	(msec.)	18	31	3
Page Transfer Time	(msec.)	10	8	1

Table 6

5. Control of Expanded storage

The primary objective with respect to using Expanded storage efficiently is to send to Expanded storage those pages that will be referenced *before* migrating to channel-attached paging devices. Several variables can be set in the IEAOPTxx member of SYS1.PARMLIB to help control the use of Expanded storage.[7] These parameters are summarized below.

6. In total, there are 1770 copies of the programs that were executed, 90 programs in the Virtual Fetch library and 1680 (28*60) programs in the dependent regions. For an arbitrary program to execute, it is 18.67 times more likely to reference a copy in the Virtual Fetch VIO dataset than a preloaded program in one of the 28 separate address spaces.

7. IBM, "MVS/Extended Architecture System Programming Library - Initialization and Tuning", GC28-1149-2, 3rd Edition, July, 1985

Criteria Parameters for Expanded Storage	
ESCTPOC	Criteria age (secs) of changed page-out pages
ESCTPOU	Criteria age (secs) of unchanged page-out pages
ESCTSTC	Criteria age (secs) of changed stolen pages
ESCTSTU	Criteria age (secs) of unchanged stolen pages
ESCTSWTC	Criteria age (secs) of changed swap-out pages
ESCTSWTU	Criteria age (secs) of unchanged swap-out pages
ESCTSWWS	Criteria age (secs) of working set pages for swap-out
ESCTVF	Criteria age (secs) of Virtual Fetch pages

Table 7

To determine when page frames are moved to Expanded storage, consider the following:[8]

- *For SWAP pages:*

  IF (HI UIC + migration age) > criteria age THEN
  page movement to Expanded storage

- *For Terminal Wait pages:*

  IF (HI UIC + migration age - user Think time) >
  criteria age THEN page movement to Expanded storage

- *For stolen, Virtual Fetch, or pageout pages:*

  IF migration age > criteria age
  THEN page movement to Expanded storage

Again, the purpose of these calculations is to send only those pages to Expanded storage that are likely to be referenced again before being migrated to auxiliary storage. The criteria age values are nearly constant; they can be changed only by changing the variables specified above in PARMLIB. The HI UIC and the migration age are dynamic, and they change constantly to reflect the current workload on the system.

6. Effects of Expanded storage

To evaluate the consequences of Expanded storage on paging, we need a model of process behavior. Let us define the following parameters that characterize Central storage:

t	time to access memory in primary storage
T	time to access secondary storage
s	fraction of the program (+ data) resident in primary storage
$p(s)$	number of page faults per memory reference as a function of fraction of program that is resident

Table 8

The effect of demand fetching is to increase memory access time from t to $t + p(s)\ T$. Figure 9 characterizes the behavior of $p(s)$.

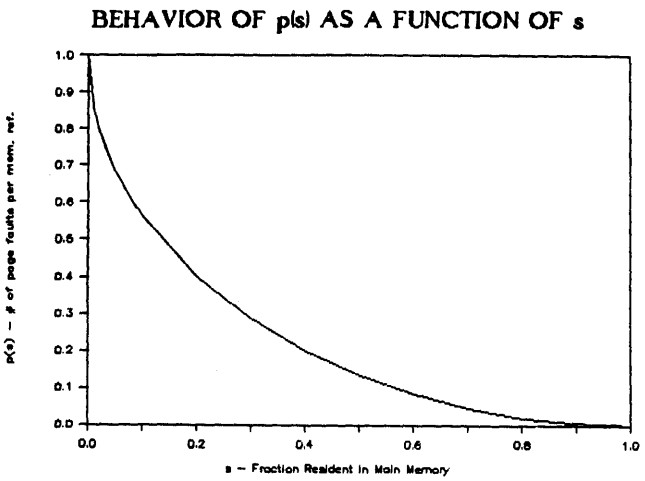

Figure 9

Coffman & Varian[9] performed many experiments on an IBM 360/50 to study empirically the effects of paging on program behavior. Their study led to several conclusions:

1. The greater the available memory, the greater the percentage improvement in page faulting.
2. Increases in memory are more beneficial than increases in page size when control frequently resides in a set of instructions or data that is small compared with the page size.
3. References to pages containing data induce substantially more paging than do references to pages containing instructions.
4. The *tail* of $p(s)$ can be approximated by

$$p(s) = ae^{-bs}$$

where

$$0 < a < 1 < b \quad \text{and} \quad a\,e^{-b}\,T << t$$

Denning[10] defines the *working set*, W, as the "minimum collection of pages that must be loaded in main memory for a process to operate efficiently without unnecessary page faults". For purposes of analysis, we must quantify the working set.. We define the working set W as that fraction of the program resident in the main memory such that the time between page faults equals the page fault service time. As an equation, we have:

$$p(W) = \frac{t}{T}$$

From the approximation of $p(s)$, we derive

8. In these formulas HI UIC is the High Unreferenced Interval Count as calculated by the system, Migration Age is the migration age calculated by the system, and Criteria Age is the value specified in the IEAOPTxx member in SYS1.PARMLIB.

9. Coffman, Varian, "Further Experimental Data on the Behavior of Programs in a Paging Environment", Communications of the ACM, Vol. 11, No. 7, July, 1968, pps. 471-474

10. Denning, P. J., "The Working Set Model for Program Behavior", Communications of the ACM, Vol. 11, No. 5, May, 1968, pps. 323-333

$$W = \frac{1}{b} \ln\left(\frac{aT}{t}\right)$$

As no guidelines appear for values of a and b, we borrow an example from Brinch Hansen[11] where $a = 0.1$, $b = 10$, $t = 1\ \mu sec$:

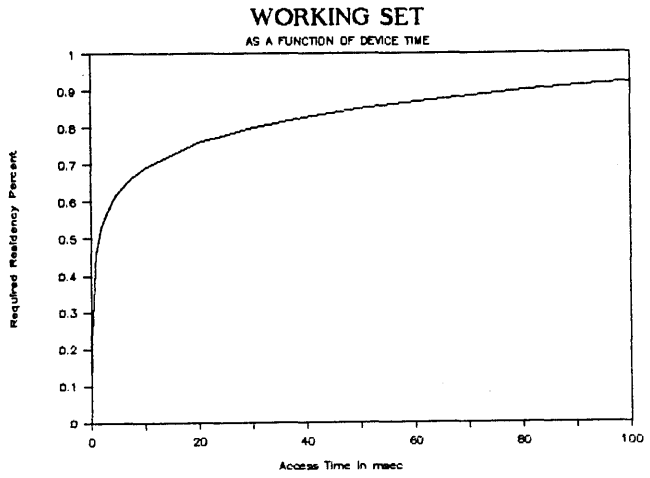

Figure 10

Figure 10 depicts the relationship between the speed of a paging device and the corresponding working set percentages (the minimum amount of program that must be present in primary storage to prevent thrashing expressed as a percent of total program). Thus, for the following set of possible paging devices with corresponding access times[12] we derive corresponding working set percentages:

Paging Devices & Access Times		
DEVICE	ACCESS TIME *(T)*	*W*
IBM 3380 disk	20-30 msec	76% - 80%
IBM 3880-11 (or 21)	8 to 10 msec	67% - 69%
STC 4305 (Solid State)	3 - 5 msec	58% - 62%
Expanded Storage	0.015 - 0.115 msec	4% - 24%

Table 11

Thus, the above example suggests that a faster secondary store (e.g., disk, drum, Expanded storage) allows a *smaller working set* per program at a given level of performance. Denning points out that a smaller working set allows a *higher multiprogramming level* with a given size memory. Therefore, Expanded storage appears to increase the potential concurrency level for a system of a fixed memory size.

The above analysis should only be used as an intuitive guide to the performance of Expanded storage, as

- No recent approximation for *p(s)* exists.
- No IBM published figures exist for memory access time *t* on a 3090.
- This analysis assumes all programs have identical values for *p(s)* and that *p(s)* is time invariant.
- This analysis does not account for Central storage requirements for page migration.

Although this section provides motivation for the use of Expanded storage, it does not answer the important question of which is better to acquire; Central storage or Expanded storage. When the 3090 series was first announced, this question was moot, Central storage was offered in one size only. The 3090 E series now provides options for Central storage. Experiments are being planned for the summer of 1987 to compare Central to Expanded directly.

We conclude this section with a quote from Denning: *"There should be enough core to contain a program's working set. There is no substitute for core."*

7. Conclusions

After careful examination, we find that Expanded storage does reduce the excessive demands on the paging subsystem. One can consider Expanded storage to be an extremely fast paging device; that is, page faulting will still occur when references are made to Central storage that cannot be resolved. However, if the referenced page frame resides in Expanded storage, the page reference is resolved at a speed that is much greater that of the more traditional paging subsystem. The best page response time for a channel-attached solid state device is reportedly less than 10 milliseconds; Expanded storage appears to be resolving page faults in the microsecond time frame. But because the next level of the paging hierarchy responds in a few *milliseconds*, there can be a sharp break in page fault resolution time in a system with fully occupied Expanded storage.

Expanded storage *can* be overcommitted. In one case where the ES Rate approached 1800 pages per second, the CPU was fully committed to serving page fault resolution (i.e. 100% CPU utilization with no throughput). The user of Expanded storage is encouraged to tread carefully in these new waters.

8. Acknowledgements

We would like to take this opportunity to thank all those IBM personnel who helped coordinate this effort; their support was essential for the completion of the project. Thanks also go to those Bell Communications Research personnel who provided both technical and administrative support. Any questions or comments on the material presented here can be addressed to one of the authors.

ABSTRACT

Increasingly, graphics are being used in management level presentations and reporting systems. It is important that graphics be used for an express purpose and not in a casual manner to assure that they honestly reflect the data and make a clear point. This paper discusses a variety of common graphical errors and offers suggestions to clarify the use of pictures to represent data.

INTRODUCTION

As performance analysts or capacity planners, our jobs center around analyzing data and conveying our findings to others. The techniques we use are usually verbal descriptions of data, tables, and pictures. Each of these techniques is useful where appropriate. Verbal descriptions can explain, interpret and express conclusions. Tables present exact information in a concise manner to allow flexible comparisons. Pictures are powerful ways to communicate comparisons and relationships. Increasingly in data processing and business in general, graphics are being used in management level presentations and reporting systems.

There are a variety of reasons why graphics are becoming more commonplace. The first reason is that they are so much easier to produce today than in the past. Prior to the days of PC's and mainframe graphics packages, the analyst had to rely on his own skill at mechanical drawing or the services of an artist or draftsman. In either instance, the process was time consuming and labor intensive. As a result, graphs were produced only after careful study of the data to highlight some particular points of value. Today, in a matter of moments, any analyst can generate reams of graphical reports and select those that seem most promising.

Another reason for the popularity of graphs appears to be based upon the belief that graphics makes a presentation more professional looking. This idea may have originated when graphics were difficult to produce, but with their proliferation as a result of inexpensive PC software, today graphics are considered no more professional than tables.

Finally, there is the belief that the use of graphics keeps the audience awake and simplifies the presentation because graphs are easier to understand than tables. Actually, such a general statement is not supported by research. In general, the literature is contradictory, with some studies supporting graphics and others supporting tables. A recent study by Dickson, DeSanctis and McBride (1986) provides some insight into the contradictory nature of some of the research. Essentially, they conducted three separate experiments of differing levels of complexity with business school subjects. Their general finding was that graphics are superior to tables in supporting decision making in only a few instances: those involving large amounts of data over time; and where the audience is presented with large amounts of data and the goal is to have them recall a few specific facts immediately after the presentation. Essentially, their conclusion was that graphics are not generically superior to tables, and the correct technique depends on the task at hand. Conflicts in the results of earlier research probably were due to the differences in the tasks being performed by the subjects.

These conclusions have a significant implication for the analyst: there should be an express purpose behind producing a chart of graph. Graphics should not be the default method of conveying the meaning of data, but instead should be used only after text and tables have been expressly ruled out as inappropriate.

THE CHOICE OF TEXT AND TABLES

In order to determine if graphics is the preferred mode of data presentation, there are some simple guidelines. Where the purpose is to explain, interpret or explain the data, text is the vehicle of choice. When the intent is to compare only two numbers, text is also an appropriate medium. For example:

> The number of concurrent TSO sessions increased from 200 in November to 225 in December.

When several numbers are being conveyed, a simple table becomes more appropriate to facilitate comparisons within the data. For example,

> The accuracy of the forecasts for CPU use by our major divisions in the past calendar year were as follows:

Manufacturing	98%
Marketing	89%
Systems	55%

In this situation, there is little to be gained by using a chart as opposed to this simple table. In addition, when the accuracy of the data is important or when many localized comparisons are being made, tables are the appropriate technique. For example, if the intent is to present the total billing of data center services for batch and each online application within each department for the company, a super table is more preferable to hundreds of trivial bar charts.

In addition, there is a class of hybrid tables such as the stem and leaf table below (Tukey, 1977).

```

This table combines a table's ability to preserve all the granularity of the data with the ability of a frequency chart to display the shape of a distribution. The numbers on the left represent units of tens. The numbers on the right represent individual observations. In this instance, there were no values less than 10 or from 10 to 19. The smallest observation was 23, followed by two 24's, a 26, two 27's, etc. Most of the values were beteeen 40 and 50, and none exceeded 58.

PURPOSE OF GRAPHICS

There are two situations where pictures are most applicable: in expressing relationships between variables, and in emphasizing the key points the analyst wants the audience to recall from the presentation. Whatever the original motivation of the analyst to consider graphics, the actual utility of graphics should be to reduce the complexity of the data by guiding the audience to make the appropriate comparisons and recognize the trends in the data. The concern in developing graphics is not to be guilty of making the interpretation of the situation more complicated. There are two essential principles to follow in producing viable graphics: First, honestly portray the data; and second, make your point as clearly as possible. Discussing these two principles will provide the focus of the rest of this paper.

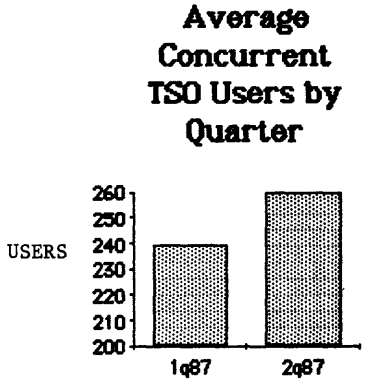
HONEST PORTRAYAL OF THE DATA

Honestly portraying the data in pictures requires avoiding those presentation errors that can lead to visual deceptions. Essentially, deception occurs when the graph or chart misleads the eye into interpreting that the relationship displayed is more or less extreme or otherwise different than is actually the case. As we produce and evaluate our graphics, there are five basic classes of these common errors: scaling, perspective and perception, standardization, data integrity, and data ordering.

SCALING

Scaling of the vertical and horizontal axis is probably the most common source of error that occurs in graphics. The types of errors that occur are essentially those of an inappropriate choice of range of values, mixing different scales on the same chart, and changing the base of the scale. In example 1a, the average number of TSO users per quarter is displayed. It would appear that in just the past six months that there has been a 50 percent growth in concurrent number of TSO sessions. However, such is not the case, because inspection of the scale of the vertical axis shows that the origin is set at 200 concurrent sessions.

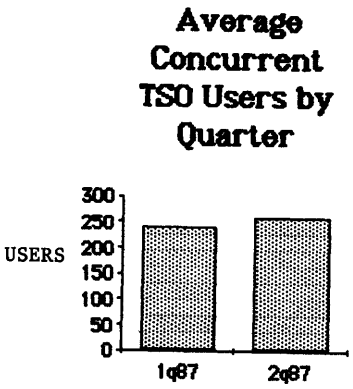
Example 1a



In example 1b, which is drawn to scale, it is clear that there has been growth in the number of sessions, but that growth is on the order of less than 10 percent. Example 1a basically exaggerated the growth in workload five fold over what would be supported by the data. For the analyst to suggest that the labeling was clear enough to have avoided an erroneous conclusion, misses the basic point: the picture must clearly represent the extent of the comparison, while the labeling is simply supporting information.

In addition, in presentations to large audiences who may not have copies of the presentation, notations and scales are often not legible; thus, the audience is left to make its interpretations and conclusions largely without the benefit of copies of the graphics. Particularly in these cases, the pictures must be able to stand alone in correctly illustrating the extent of the comparison or the trend of the data.

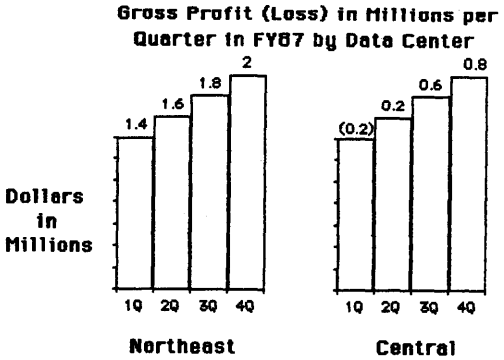
Example 1b



As a general rule, all charts which seek to illustrate the relative differences in values should explicitly show the zero point without a broken scale. One possible exception where a broken scale would not compromise the integrity of the chart is where the purpose of the chart is to highlight similarities and differences in the slopes of a relationship between two variables.

Not all changes in scaling are as easy to catch. In example 2, we see that the gross profit for two data centers are being compared. The initial interpretation is that each center has experienced healthy profits over the last four quarters. Implicit in this chart is that the scales are the same for each data center, which is not true. Hidden, for the audience to discern in the short time a slide is displayed, is the fact that the vertical scales are different in each comparison and, in fact, in the second data center, the gross profit was negative in the first quarter.

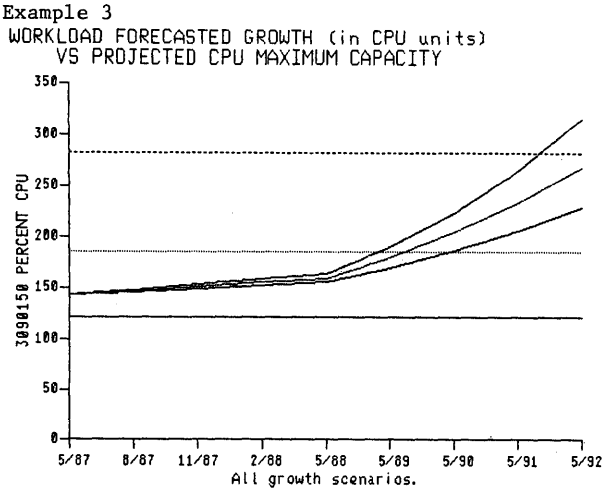
Example 2



Problems in scaling are not limited to the vertical axis alone. The following illustration, in example 3, was generated using a major capacity planning package and appears to suggest that the current configuration will meet the company's needs over the next two years

but will then quickly run out of capacity. However, the scale shifts from quarterly data to annual data halfway along the scale. Obviously, the data center configuration is not really in imminent need of more hardware, and, in fact, will experience a degradation in performance much more slowly than is implied by this graph. Some analysts might suggest that such a chart would be appropriate with adequate labeling or by slightly separating the graphs. Yet, particularly if such a graph is intended for a foil or slide presentation, such annotations would be largely unseen by the audience and still mislead the viewer about the extent of the basic trend of the data.

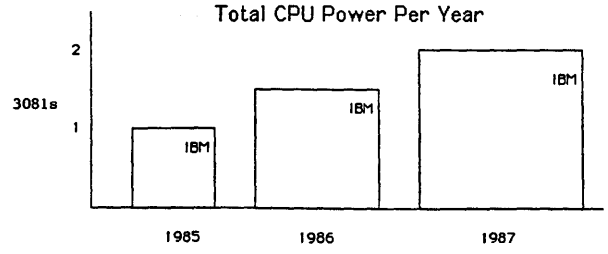
Example 3



PERSPECTIVE AND PERCEPTION

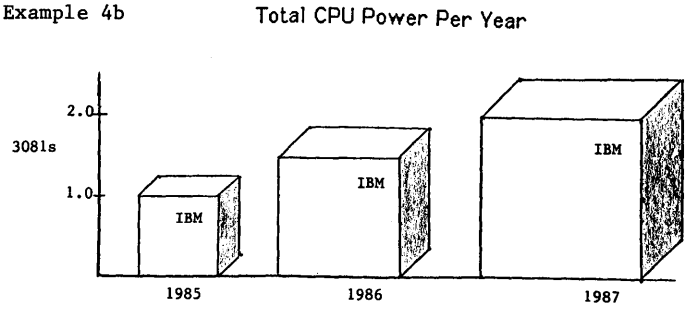
Two and three dimensional graphs are becoming more commonplace because of their ready presence in graphical and drawing packages. In general, these techniques are used to make the presentation "more interesting." Yet, the use of such techniques probably lead to more problems than they overcome. The general difficulty occurs when one dimensional data is presented using figures that change in two or even three dimensions at the same time. In addition, their use in these situations leads to a considerable increase in clutter with no increase in information being conveyed. In the next example, the analyst hoped to stimulate the audience's interest by presenting some "snazzy pictures" to keep the audience awake. Rather than use a table or a simple bar chart, he decided to use pictures of CPU's to portray the growth in the data center's compute power.

Example 4a



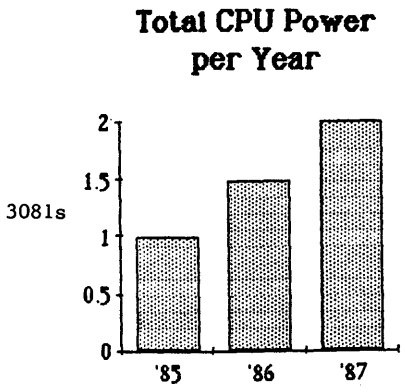
In example 4a, the height of the CPU corresponds to the total compute power at a given point in time. Unfortunately, the eye tends to interpret and compare differences in total area from one time period to another. In this simple comparison, where the total compute power doubled, the graph portrays two pictures that differ in area by a factor of four. In this instance, the audience may understand and be able to recall that the growth in compute power was considerable. It is unlikely that they will correctly recall the extent of that growth and will likely overestimate the size of that growth.

Example 4b



With the advent of three dimensional graphics packages, this type of error can be even more compounded with a three dimensional representation of the CPU growth as in example 4b. In this instance, although the size of the data center doubled, the volume of the CPU graphic increased by eight fold. In neither of these two cases has the analyst been true to the data. Yes, pretty pictures have been created, but the audience has been mislead and nothing was added beyond the much simpler presentation of example 4c. Most likely, the analyst would have been horrified at a suggestion to "massage" the data to overstate the change that had occurred. Yet, the use of these techniques has the same effect on an audience's recollection of the data.

Example 4c



Both two and three dimensional examples also suffer from an additional failing relating to the spacing of the x axis. Because the spacing between each figure is constant and each figure is progressively larger, the distances between the years, although of equal size, are not equally represented further emphasizing the most recent time interval.

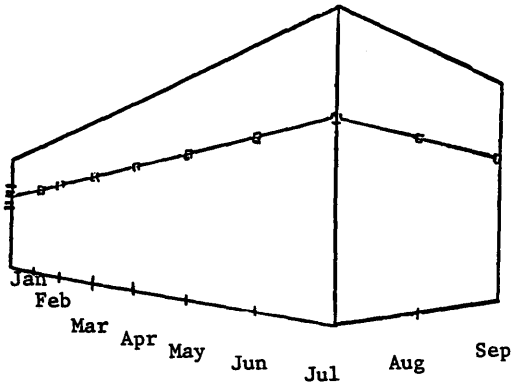
Example 5a shows another technique used to enliven graphics. In this situation, the analyst was attempting to illustrate the number of hardware failures that occurred prior to and immediately after switching to another hardware vendor's DASD. Note that the time the hardware change occurred is in the foreground. Through the use of perspective, the analyst was able

to convey the mistaken notion that the number of outages has fallen off since the hardware change, even though the number of outages did not change significantly.

Example 5a

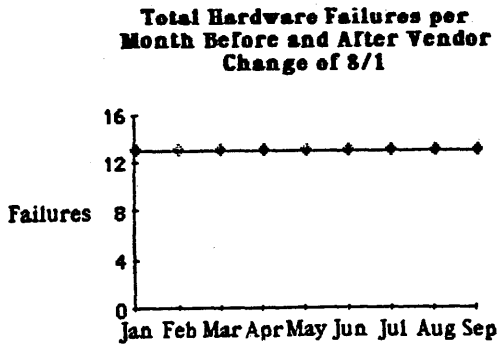
Total Hardware Failures per Month

Before and After Vendor Change of 8/1



Example 5b restates the data in a simpler fashion, and it is clear that there is no significant increase in number of hardware outages after the change of vendor. In conclusion, the use of perspective has little to offer the analyst interested in accurately portraying data.

Example 5b

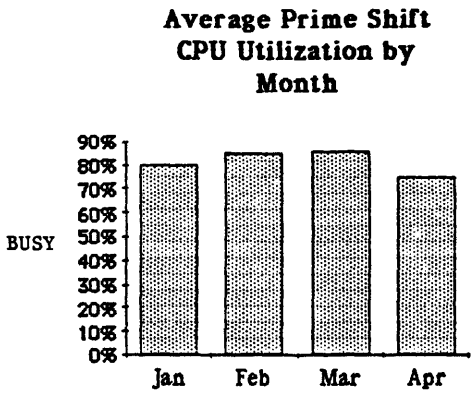


STANDARDIZATION

At times, an analyst will neglect the fact that value of a number can change over time. A common situation that plagues business in general relates to money and inflation. For example, if one were comparing the budgets for data processing from 1967 to the present, the increases in expenditures would be grossly overstated in excess of 300 percent because of inflationary effects. Thus, economists rely on using standardization to create constant dollars.

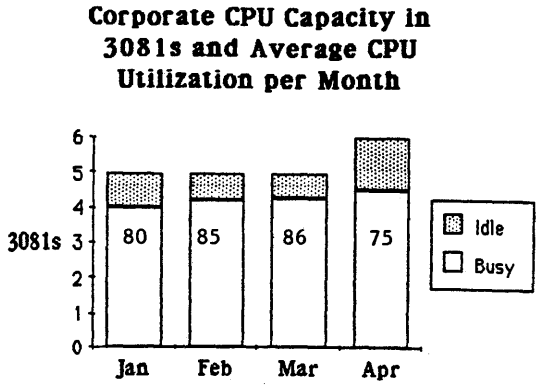
A more specific situation that can occur in data processing related to trying to represent available capacity when the configuration changes. In the following example, 6a, the data center is tracking average CPU utilization. At first glance, it appears that there was a drop in workload in April. The initial suggestion might be that due to vacations coinciding with Easter, the workload was down. However, what actually happened was that a field upgrade had increased the capacity of some of the processors, and, in fact, the number of service units processed actually increased. What is missing is some manner to indicate changes in the size of the base; in this situation, the number of standardized 3033 or 3081 processors. Perhaps the simplest technique would be to annotate the April entry to indicate the increase in capacity.

Example 6a



An alternate implementation, represented in example 6b, is to use a histogram, the height of which indicates the total CPU capacity of the center and employs stack charting to represent the proportions idle and busy. In this example, it is possible to jointly track the capacity of the data center, the extent to which the CPU is in use, and aggregate CPU use.

Example 6b



One final alternative is to present the rather simple table in example 6c.

Example 6c

Corporate CPU

Capacity in Equivalent 3081s

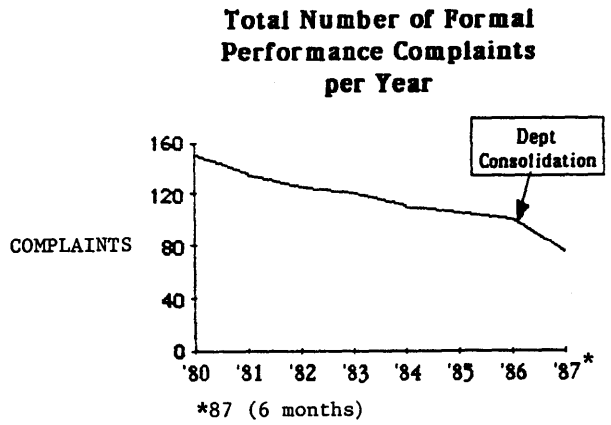
and Average Prime Shift

CPU Utilization by Month

	Jan	Feb	March	April
Total Capacity in Equivalent 3081s	5.0	5.0	5.0	6.0
% Idle	20	15	14	25
% Busy	80	85	86	75

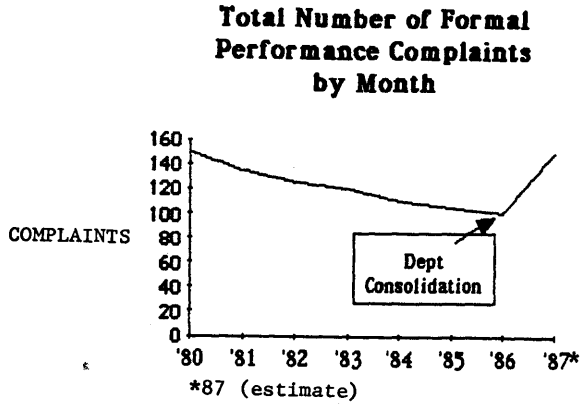
Another error can occur that mixes the effects of changing the scale of the horizontal axis with raw count data.

Example 7a



In example 7a, the analyst has plotted the number of customer complaints about performance, particularly emphasizing the number of complaints under the long regime of his predecessor as compared to those under his own relatively short reign. On first blush, the current analyst has had a noticeable effect on reducing complaints, much more so than had the earlier analyst. However, the situation is not as rosy as it appears, since the data for the prior analyst represents counts for 12 month periods while the last interval represents the past six months. Given no other additional information, it is likely that the number of complaints for the remaining six months will equal the prior six months, and, when this adjustment is made for the current year, the graph is as presented in 7b.

Example 7b

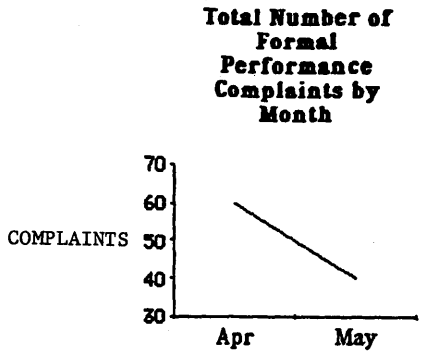


Obviously, the new analyst is not yet as effective as his predecessor.

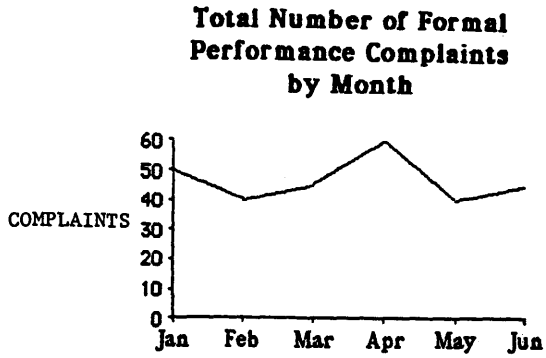
DATA INTEGRITY OR PRETEST/POST-TEST

Often in performance analysis, we must make evaluations of the effectiveness of some system or operational change on the net performance of the data center. At its simplest, there is a pretest, we make the change, we test again, and compare the results. The fallacy that can creep in is procedural in nature and can be reflected in simple graphics used to present the results. Example 8a attempts to summarize the effects of a 322 exit to prevent run-away applications by automatically canceling a session that uses excessive amounts of CPU. There appears to have been a rather significant reduction in the average CPU time per session, although to a large extent this reduction is over-represented by starting the Y axis at 30 rather than 0. However, the analyst failed to consider if the reduction in CPU time was greater than the normal variation in CPU time per session. By plotting several months prior, as in example 8b, it is clear that the current level of CPU consumption after implementing the 322 exit is not significantly different than the months immediately prior. This could also be validated with a traditional test of significance. In sum, whenever evaluating the effect of a system change on performance, it is necessary to evaluate more data than just the two time periods immediately adjacent to the point of change to assure that the change is significantly greater than the normal variability.

Example 8a



Example 8b

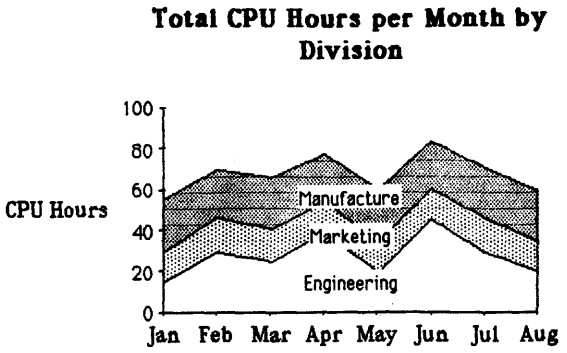


DATA ORDERING

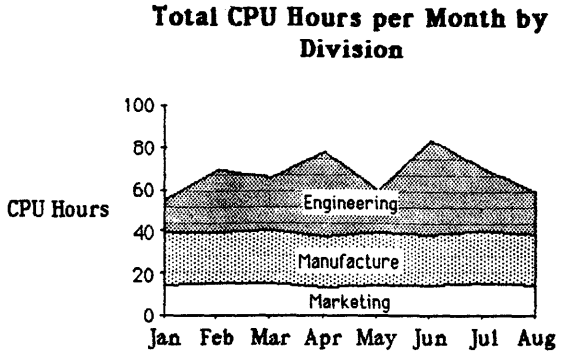
Care must be taken in the order in which data is presented in a chart. One type of chart that is particularly prone to this type of problem is the multiple strata surface chart. This form of rectilinear coordinate chart portrays the component parts of a total that can be expressed either in absolute numbers or in percentages.

Examples 9a and 9b show two very different looking charts. The first suggests very unstable data for all three divisions. In contrast, the second reveals that only the Engineering Division's use of the CPU has been erratic over time, while the other divisions have had rather stable CPU use. However, both of these examples are based on the same data with the only difference being that CPU use by the Engineering Division is presented at the bottom of the chart in the first example and at the top of the chart in the second example.

Example 9a



Example 9b



When using a multiple strata surface chart it is important to recognize that the basis for reading the values of the strata is the distance between the plotted lines and not the distance of the lines from the baseline. In this type of chart, only the total and the bottom strata can be read from the baseline. Therefore, the point being made by the analyst is the contrast in the fluctuations in one strata relative to the consistency in the others, the strata exhibiting considerable fluctuations should be placed at the top. On the other hand, if the major point being made is that the overall change is due to the monotonic change in one of the strata, that strata should be placed at the bottom most strata.

PRESENTING THE DATA CLEARLY

There are several practices that can make the point of a graphical presentation easier to determine: avoid pie charts; avoid the moire effect; use care if color is employed, minimize unnecessary clutter.

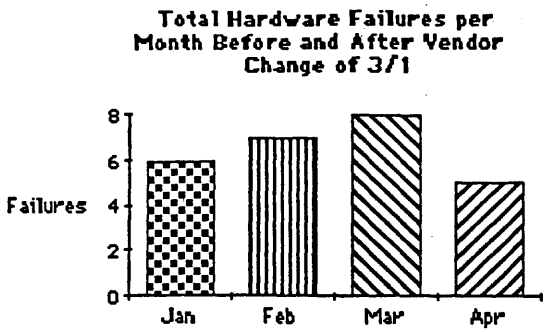
AVOID PIE CHARTS

Although commonly used and produced by virtually every graphics package, pie charts are generally frowned upon by statisticians. One of the general failings of pie charts is the lack of any explicit scale to evaluate the size of a particular slice. This is the reason that so many pie charts have categories explicitly labeled with their values. Unless the analyst is attempting to reinforce the notion that some component of the whole is equal to half or perhaps one quarter, there is little to recommend the use of a pie chart. Probably the only picture worse than a pie chart is a page full or pie charts with the expectation that the audience will compare one pie chart to another. Pie charts are a terrible choice where the intent of the analyst is to compare and contrast multiple percent distributions. The only singularly prevailing reason to use a pie chart in a presentation is that your boss insists upon it. A table or a 100 percent bar or column is almost always preferable. If you must use a pie chart, restrict its use to no more than four categories, and never use multiple pie charts to illustrate differences in distributions.

AVOID THE MOIRE EFFECT

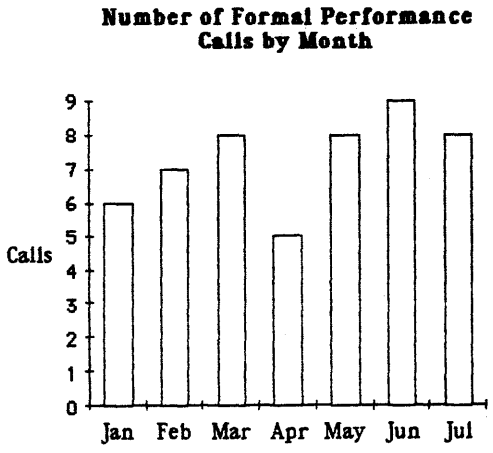
This effect describes the situation where a picture appears to pulse, vibrate or move. When such an effect is present in a graph it distracts the audience from the message of the graph. Essentially, the Moire effect occurs when patterns are presented with extreme contrast as depicted in example 10a. This effect is seen with the use of hatching to distinguish subgroups, and has become increasingly prevalent, particularly with non-color graphics. There are two remedies which can be used singularly or in tandem: preferably use words to label the subcategories; and avoid stark contrast by using shades of grey.

Example 10a



The second situation where the Moire effect can occur is depicted in example 10b. In this situation, the graph appears to move because of the close equal spacing of the boundaries of the histogram and their separating spaces. In this situation, the problem can be avoided by spacing the bars closer or farther apart than the width of the bars.

Example 10b



USE WITH COLOR

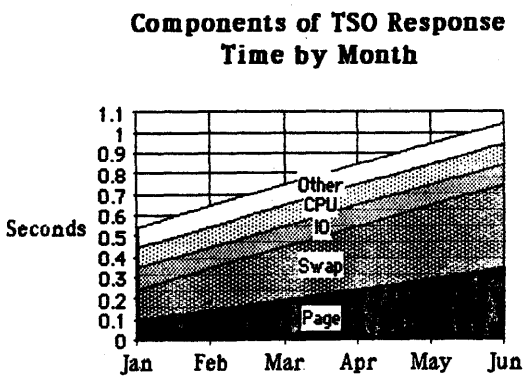
The use of color can be a two edged sword. If you have access to color graphics, color can be used to avoid the Moire effect caused by hatching. However, the inappropriate use of color can make an otherwise admirable graphic unreadable. Particular care needs to be made with slides using a dark background, such as when you are attempting to simulate the appearance of a

3179 color graphics terminal. Among the worse colors to use for text are the dark colors, like a deep red or blue, which do not project well at all. Instead use the light pastels to assure that the picture can be read. Since one male in eight experiences some degree of color blindness, the colors green and red should be avoided for important contrasts in the graphics themselves.

MINIMIZE THE CLUTTER

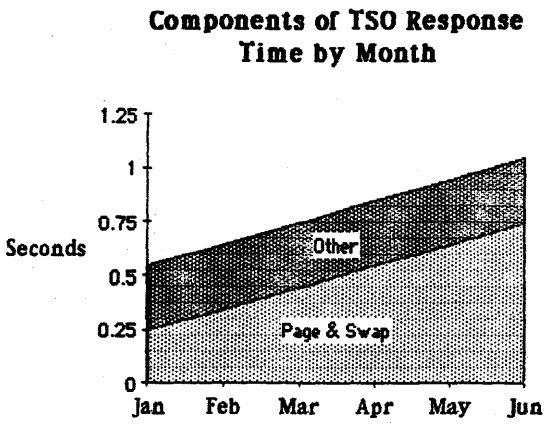
It is important to distinguish between graphics used for data analysis and those used for presentations. When graphics are used for analysis, the skill of the analyst can usually see through the excessive data and presentation clutter to the underlying information. In order to provide useful presentation graphics, the analyst must discern the message he intends to convey with the graph, eliminate or consolidate unimportant data, remove grid marks, and simplify the scaling so the information is not overwhelmed with the supporting structure of the graphic. In example 11a, we see an illustration of a rough contour chart which is reviewing trends in the wait reasons for TSO response time.

Example 11a



It suffers from too many insignificant wait reasons, too many scale annotations, and the clutter of grid marks, which are only useful for drawing a graph by hand. The surface chart in example 11b focuses on conveying that the growth in TSO response time is due primarily to a growth in the time spent paging and swapping. It accomplishes this task by first consolidating the less significant wait reasons, and presents the page and swapping delays adjacent to the horizontal axis to facilitate comparisons of the growth in page and swapping delays over time with the change in overall response time.

Example 11b



CONCLUSION

The use of pictures to represent data has become increasingly prevelant in management level presentations in data processing. This is due largely to the perception that the use of charts and graphs makes a presentation both easier to understand and more professional in appearance. Because of increasing use, it is more important that a graph accurately and clearly represent the data at hand. To this end, a variety of common graphical errors have been highlighted, and some suggestions have been made to clarify the use of pictures to represent data.

AN IMPLEMENTATION OF A GRAPHICAL MANAGEMENT INFORMATION SYSTEM USING SYMPHONY

DYNA WILSON
CoreStates Financial Corporation

ABSTRACT

Hard copy monthly status reports for Performance and Capacity Planning can never be timely given the nature of their construction. Time is required after month end for mainframe data extraction. Data reduction must be accomplished to make the data relevant. And then the data must be made understandable to non-technical users and prepared for presentation to management. Just when the report is being completed, we discover a missing data item. We wait. Finally, the report is in final form and our job is done. We send the completed report to central word processing for last minute corrections, duplication and distribution. They give it three day turnaround.

The monthly status report is out in three weeks. Not a bad month.

At CoreStates, we have implemented a PC based graphical application which enables key managers to view performance and availability data as it becomes available at month end, long before the monthly status report is completed and distributed.

An implementation of a graphical Management Information System for Capacity Planning and Performance using Symphony graphics is described.

1. INTRODUCTION

CoreStates Financial Corporation is the 36th largest bank holding company in the United States when measured in assets. However, we are in the top ten of the largest VISA issuers, international funds transfer banks, and check processors. We are the proprietors of MAC which is either the first, second or third largest shared ATM network in the country, depending on which measure you prefer. Each day, we process over a million IMS transactions, 100,000 CICS transactions and 250,000 TSO transactions. Nearly 200,000 batch jobs are required each month. This is accomplished with 5 IBM main-frames (2-3033, 3-3081) and 180 gigabytes of DASD. More than 8000 terminals, ATM's and Point-of-Sale (POS) devices are supported on our network via 37x5's, using VTAM and NCP, on some 180 leased lines. Additionally, 60 Tandem processors are supported as switches for MAC, POS, International and Funds Transfer operations.

The Performance and Capacity Planning Group at CoreStates is tasked with generating, accumulating and analyzing performance statistics across all business areas for all systems. We are tasked with enduring as opposed to reactionary performance management, bottleneck identification and prediction, and strategic capacity planning. As part of a mobile reserve, we are called upon to provide data for reactionary problem resolution and serve as translators for management.

To give us a firmer foundation for our translation duty, we began publishing a monthly management briefing book about three years ago. It contains performance and availability statistics presented in graphical and tabular form for the hardware, software and communication components which support key business elements within the corporation. Appropriate historical information is presented with each statistic to define perspective and demonstrate trends. The briefing book also provides a vehicle to transmit the number and type of installed equipment, financial performance of various groups or products, and staffing levels. In accordance with its intended purpose of presenting concisely and at a high level those issues of current interest to management, its contents are free to evolve in concert with corporate business directions.

This year, we have created an interactive Graphical Management Information System (GMIS) so that the performance and availability graphs found in the management briefing book are now available in the managers' offices within a few days of month end. Both the hard-copy management briefing book and GMIS are effected using Symphony software which is licensed by Lotus Development Corporation. Table 1 lists the graphical reports which are included in GMIS.

2. SYSTEM OVERVIEW

GMIS is an interactive macro driven graphical display system which uses the Symphony menu interface. The customized menus, appearing on the Symphony command line, are a two level hierarchy and can be traversed via single keystrokes. As each menu choice is highlighted by the cursor, a description of the action is displayed on the line above. The main menu is responsible for exiting GMIS, invoking a continuous slide show or selecting a submenu. The entry screen displaying the main menu in the command line is shown in Figure 1. Each of the second level menus gives choices of specific graphical displays as well as a return to the main menu. The menu hierarchy is depicted in Figure 2. To display any of the 28 graphs available, the user first displays the submenu that contains the graph title by entering the first letter of the submenu name while in the main menu. At the submenu display, the user enters the first letter of the graph title to display the graph. Alternatively, the user may move the cursor to highlight any entry and enter return. To terminate any graphical display, the user enters any single keystroke and is returned to the submenu from which the graph was invoked.

GMIS can be loaded and invoked by a single keystroke from the DOS prompt. However, those managers whose PC's support multiple sessions usually choose to leave GMIS loaded and active in one window. GMIS can also be exited and provide a return to DOS with a single keystroke from its main menu.

3. SYSTEM ARCHITECTURE

GMIS is supported by Symphony v2.1 and is run on MS-DOS compatible personal computer with 256K internal memory and graphics board. It is also supported by Symphony v2.1 on the IBM 3270PC with 640K internal memory and graphics board running the 3270PC Control Program.

GMIS is a single self-contained Symphony worksheet file. The worksheet file is logically divided into four sections: Entry Screen; Main Menu Macros; Submenu Macros; and Data. The graphs are generated from Symphony graph configuration files and displayed via calls to predefined graph windows. The graph configuration files and window definitions are stored internal to the Symphony worksheet file. The Main Menu Macros and the Submenu Macros serve to display the command line menus and descriptions, automate calls to specific windows, and control program flow.

4. INITIALIZATION

GMIS is loaded from the DOS prompt by entering an "S". This instructs DOS to run a batch file named S.BAT which is stored in the root directory. The batch file as exhibited causes the correct color driver to be loaded, changes the current directory to SYM and invokes Symphony from that directory. When Symphony is exited, it changes the current directory to the root directory.

```
S.BAT
  mode co80
  d/sym
  symphony
  cd/
```

Two settings must be preset and saved in the Symphony configuration file to cause GMIS to self-load and self-invoke. First GMIS must be specified in the Symphony configuration file as the worksheet to be loaded automatically. This is accomplished by selecting CONFIGURATION from the SERVICES menu and entering GMIS at the AUTO prompt. Second, the macro which initiates GMIS must be specified as the macro to be executed when GMIS is loaded. This is done by selecting SETTINGS from the Symphony SERVICES menu and entering the initial macro name at the AUTO-EXECUTE prompt.

5. IMPLEMENTATION

Each menu appearing in the command line is precisely structured in a portion of the spreadsheet that is labelled with the menu name. In this structure, each menu choice is entered horizontally, one per cell, with no embedded blank cells. The first cell beneath each menu item contains the description which displays when that menu item is highlighted. Below this, Symphony macro commands are entered vertically with the first blank cell signalling the end of control. The macros which implement the following functions are described in detail: branch to submenu; display a specific plot; return to main menu; continuous slide show; ending GMIS; and error handling.

Branch to a Submenu:

```
NETWORK
Data, Audio, Voice
(menubranch menunet)
```

The menu choice appears in capitals, the description of the action which is displayed when this choice is highlighted appears in the second line and the program control is passed to an area labeled "menunet".

"Menunet" contains the submenu choices for the data, audio and voice network graphs.

Display a Specific Plot:

```
DOMESTIC
Domestic Network Availability
(paneloff)
(services)wunetdom
(?)
(services)usmain
(home)
(panelon)
(menubranch menunet)
```

Lines 1 and 2 display the submenu choice and description. Line 3 causes the command line display to be suppressed during macro execution. Line 4 calls the SERVICES functions of Symphony to display a previously defined window named netdom. In this case, netdom is a graph window which contains a 12 month domestic network availability graph. The (?) in line 5 allows the macro action to be suspended while the user is viewing the graph. When the user enters a keystroke signalling that the user is done, the GMIS introduction screen, located at the home position of the main window, is displayed. Command line display is enabled in line 8 and control is passed to the area labeled "menunet" in line 9. "Menunet" is the area containing submenu choices and macros for the network category. At this point, the command line will contain the customized menu for the network category and the user is free to make another choice.

Return to Main Menu:

```
RETURN
Return to Main Menu
(branch /m)
```

Returning to the main menu from any of the submenus is accomplished through a straight forward branch to the initial macro which displays the main menu.

Continuous Slide Show:

```
SHOW
Continuous Graphical Display
(window)
(wait @now+@time(0,0,10))
(branch show)
```

Lines 1 and 2 display the menu choice and description. Line 3 causes Symphony to display the first previously defined window it encounters. The wait command in line 4 causes execution of the macro to delay for 10 seconds. At the end of 10 seconds, a branch to the area labelled "show" is completed. "Show" is line 3 of this macro. At this execution of the window command, Symphony displays the next previously defined window and in the case of the last defined window, wraps around to display the first defined window. Thus, every 10 seconds, a new graph appears on the screen and continues until the user effects an interrupt via a cntrl-brk.

Exit from GMIS:

```
END
Exit to DOS
(services)ey
```

A call is made to the SERVICES command to exit Symphony. Control is returned to the S.BAT file which returns the user to the root directory of DOS.

Error Handling:

```
(esc)
(paneloff)
(services)wumain
(home)
(panelon)
(branch /m)
```

If an error is encountered during the execution of any macros, control is passed to the above macro. Line 1 causes the error to be cleared. Lines 2-5 suppress the command line display and return the window display to the introductory screen. Line 6 transfers control to the area labelled "/m" which reinitializes GMIS. To effect the branch to the error handling routine, it is necessary to label its location (eg., /e) and include the following command in the initialization macro: (onerror /e). Note that when the user ends the slide show via cntrl-brk, GMIS is reinitialized through this error handling routine.

6. SYSTEM SECURITY

Protection of the system against inadvertent or intentional change is afforded with a two step process. First, GLOBAL PROTECTION is set to yes from the SETTINGS selection appearing in the SERVICES menu for the entire worksheet. This prevents updates to any cells. To ensure that no one changes this setting, the worksheet must be password protected. This Lock is entered from the SECURITY option of the SERVICES SETTINGS menu.

Another command sequence in Symphony allows all the macro and/or data areas to be hidden from the user's view until the password protection is unlocked and the setting manually changed. To make the macro and/or data areas non-viewable, set the OTHER option in the MENU FORMAT selection to HIDDEN and select the entire macro and data range. This must be done while the worksheet is free from password protection and the Global Protection has been released. Once accomplished, the password is activated as described previously. The password is then required to allow the users to view the protected macro and data areas.

7. MONTHLY MAINTENANCE

At month end, data is entered into some half dozen Symphony worksheets for analysis and preparation of the hard copy Management briefing book. As each of these worksheets is updated, the information pertinent to GMIS can be conveniently copied to the single GMIS worksheet, overlaying only the portion of the GMIS worksheet which is being updated. Thus, for example, if for some reason batch performance reporting is delayed, GMIS could still be distributed in a timely manner with updates to all the graphs except the batch performance. The batch performance would remain at the prior month level.

8. CONCLUSION

GMIS has been embraced by CoreStates Managers as a vehicle for timely monthly reporting. They enjoy its speed and user friendly menu driven format. As such, GMIS has proved to be a low-cost, low-maintenance solution to performance standard reporting.

THE NEED FOR A NETWORK MONITOR

Phil Bodley
TSB (England & Wales) Bank plc

ABSTRACT

This paper describes why a non-IBM user with large mainframe installations and an extensive network decided to buy an independent network monitor.

It starts with a horror story for capacity planners, but promises a happy ending.

Some network managers and capacity planners may draw comfort by realising how easy their lives are by comparison. Others may find some disturbing similarities with their own installations, which might prompt them to consider a similar solution.

1. PLENTY OF NETWORK CAPACITY . . .

A new central complex, new programs, and a new network were installed in 1980 to replace an earlier system. The replacement network served to connect the 950 high street branches of the bank with a new computer centre at Wythenshawe, a suburb of the northern city of Manchester. The capacities of the replacement mainframe and network were more than adequate for any peaks of traffic in the forseeable future; this was essential because all transactions in TSB branches are processed online and in real time i.e. whilst the customer is present (as they have been for many years).

The new central complex was powered by a Sperry 1100 mainframe, theoretically capable of processing 70 transactions per second.

See Figure 1 for a simple diagram of the network.

Each teller position on the counter of each branch was equipped with an intelligent Burroughs Workstation comprising processor, screen, keyboard, security card reader, passbook printer, and data cassette for program loading. Additional workstations were installed for "back-office" use, making some 4500 workstations in total.

Three or four neighbouring branches were multidropped onto a 2400bps line. Several such lines converged on a regional concentrator site containing between three and eight Burroughs CP9558 concentrator computers. There were 38 such concentrator sites housing 150 concentrators. Each concentrator handled the traffic from two of the incoming 2400bps multidrop "downstream" lines. If a concentrator failed then its downstream lines could be switched to adjacent concentrators by an intelligent matrix switch (IMS) operated remotely from Comms Control at Wythenshawe. Workstation transactions were logged by the concentrators before being passed up to the computer centre on 4800bps "upstream" lines of which there was at least one for every three concentrators.

All well and good.

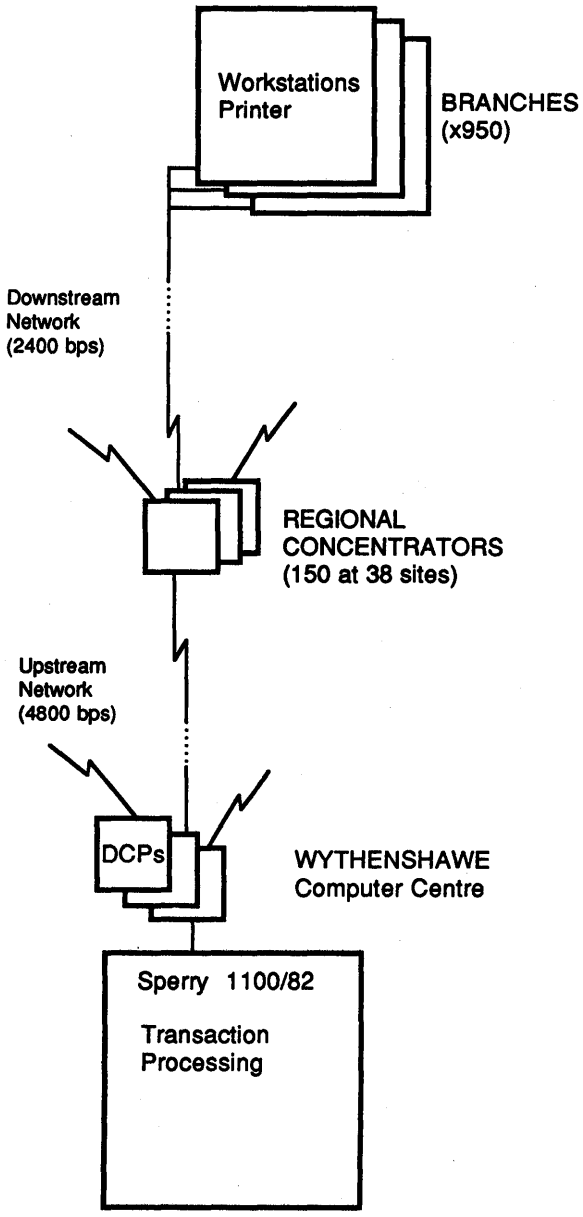

Figure 1. 1980 Network

2. . . . AND HOW TO USE IT UP . . .

Initially the traffic on the network consisted of the sort of basic banking transactions that one might imagine, covering, for example,

- deposits
- withdrawals
- enquiries for account balance and other details
- opening or closing an account
- amending a standing order

In addition, the concentrator (not the mainframe) provided some transactions to assist the teller:

- a list of transactions for the day (to help resolve any balancing problems)
- a menu of all possible transactions

The transaction traffic was confined to weekday prime shifts, peaking at around 10 a.m. and again mid afternoon, with Friday mornings generating the heaviest load. The replacement network had more than adequate capacity for these peaks.

Overnight the computer centre processed the transactions associated with clearing cheques, paying standing orders, and paying loan instalments. The branches needed daily reports of any exception conditions that arose overnight, such as cheques 'bouncing'. The network was soon being used to distribute those reports. The concentrators played the major part in this, by firing special enquiry transactions to the mainframe. The mainframe would respond to each of these transactions by returning a multiple-block response containing the report lines. On receipt of a particular report for one of its branches the concentrator would format the report and transmit it downstream to the printer in the branch. Quite a load on the network. Fortunately, report distribution for the day was designed to be completed between 0600 and 0800 whilst the network was otherwise idle.

By and by more branch reports were conceived and implemented. Good job the network and mainframe had the capacity before 0800, and capacity during prime shift to cover reports that had earlier fallen victim to paper wrecks, printer failure, or some other fate.

All the time the online system serving the branches was being enhanced, to provide such facilities as mortgage processing, foreign exchange, online customer details, credit scoring for loan applications, and many more. Some new facilities involved additional transactions, others increased the message lengths of existing transactions. Hence more prime shift workload for the network.

Then cash dispensers arrived, online real-time of course. So now the network had to support the additional workload of customers enquiring for their up-to-the-minute balance before withdrawing their cash!

The cash dispensers fronting onto the street were then supplemented by nine hundred customer-operated autotellers inside many of the branches. These machines not only allowed cash withdrawal, but also deposits, enquiries about standing order mandates and payments, printing of mini-statements and, most significantly, printing of complete up-to-the-minute statements. The additional prime shift traffic on the network caused by customers browsing through their standing orders or perhaps getting a statement printed 'nice and conveniently' can be imagined.

It is also not hard to imagine how the polling overhead and poll delays might have been increasing as all these extra devices were configured on the network. These weren't the only extra devices . . .

All this time the Bank's volume of business had been increasing. Some of this growth was steady, such as the upward drift in the average number of transactions per account per year, whilst other growth was explosive, such as taking on 0.75 million new cheque accounts in a single year. Naturally this led to much more network traffic, and also placed a strain on the existing population of workstations, so more were installed, further increasing the polling overheads.

At this point the mainframe was virtually collapsing under the weight, and had to be rapidly upgraded. Even before this could be done its overnight processing capacity became exhausted, so the creation of the all important daily reports ran late. Hence the transmission of the reports via the network to the branches could not always be completed, or on some black days not even started, before prime shift. Saturation. So when the branch staff found no reports, what was their natural reaction? To flood the system with enquiry transactions, firstly to request transmission of the missing reports, and when that was unsuccessful, to enquire for the very details from the database which the reports would have given them. Total saturation, relieved only by upgrading the mainframes and reverting report transmission to its normal early slot. Serious capacity planning got the boost it needed.

The extra workstations and the autotellers mentioned earlier were not the only aspects of change in the network configuration. It seemed forever volatile. Concentrator sites were closed or moved because the lease had run out, or because of redevelopment, or because of the threats of local civil unrest, or whatever. New branches were opened, some branches were closed. Branches connected to one concentrator site had to be switched to another to fit in with company reorganisations and regional boundary changes. Thus traffic rates would be waxing through one node of the network, and theoretically (!) waning in another.

One of the more significant changes to the configuration stemmed from adding to the network the 230 branches in London and the South East corner of England, and in the Channel Islands. For historical reasons they had previously been served by a separate online system which was incompatible with the Sperry-based system used elsewhere. A fully integrated system was a high priority goal. A concurrent requirement to provide complete disaster standby for the branch banking system was satisfied by the construction of a functionally identical computer centre at Milton Keynes (a new city 70 miles northwest of London), linked to Wythenshawe by very high speed lines. It was to this second centre that the 230 branches were connected, via thirty new concentrators. The branches retained their existing terminals until they could be replaced with the standard Burroughs workstations. Good job this was done quickly. The old terminals were dumb, so the concentrators had to emulate all the functionality of the Burroughs workstation, and the downstream lines were saturated with screen images. Hardly suprisingly the response times were poor, until the branches received their new kit.

Once the new computer centre had settled down, some of the Wythenshawe workload was transferred to Milton Keynes. Thus eleven hundred branches became connected through 180 concentrators to both computer centres, but with each centre normally handling the traffic from its half of the country.

Still the configuration changes continued. Now, since part of the configuration data is held in concentrator software there was seen to be an advantage in using the network to download that software. Hence a File Transfer facility was developed, adding a workload to

the upstream network and concentrators (usually at offpeak times, fortunately).

Jointly implemented with File Transfer was the Burroughs Datascope facility. This enabled technical staff at the computer centres to remotely inspect the content of any file, including the system incident log, on any concentrator to help diagnose hardware or software problems. Another workload on the upstream network and concentrators, not necessarily confined to offpeak times.

Talking of diagnostics, the reliability of the cash dispensers is not only high profile, but also jeopardised by their electro-mechanical nature, and by fish-and-chips, curry sauce, and other street hazards. To enable failed machines to be restored to service as quickly as possible it was considered essential to know the state of all autotellers all the time. This was achieved by implementing bi-directional status monitoring; the autotellers tell the mainframe if they are having a problem, and the mainframe can periodically probe those that seem OK to check that they are still there and feeling well. With 1,100 machines to mind this became yet another workload on both the upstream and downstream networks and the concentrators.

All the while the range of facilities available to the branch staff continued to expand. What a lot of transactions to choose from! Unfortunately screen formats and vetting procedures for each type of transaction consume memory in the workstations. Back in 1979, when the workstations were chosen, 96K seemed very generous. You've guessed: insufficient memory. The solution adopted was for the concentrators to hold the screen formats and vetting code for the less frequently used transactions, and then, when required, to download them to an overlay area in the workstation memory. Thus a potentially substantial additional workload was imposed on the concentrators and downstream network during prime shift.

And still the developments rolled on.

Soon came CHAPS (Clearing House Automated Payments System) enabling large value (£10,000+) money transmissions between TSB and the other banks. Not high volume, but still an additional network workload.

Burroughs B25 micros were introduced to administrative centres and certain branches. These posed a threat to the system because they are capable of firing off a whole volley of online enquiry transactions at the touch of a button, impacting both upstream, concentrator, and downstream.

Software and communications links were put in place to allow TSB Scotland and TSB Northern Ireland cash card holders to use the TSB England & Wales cash dispensers, and similarly to allow Trustcard (VISA) holders to be advanced cash. More traffic.

A recent development under trial permits the use of Sperry's Mapper (4GL) from designated terminals. Another potentially heavy workload.

There is much else afoot, including reciprocal autoteller arrangements with other banks. The good news: our customers will use their autotellers, so less network traffic for us. The bad news: their customers will use ours . . . . and there are more of them!

Figure 2 shows the latter-day shape of this heavily loaded network.

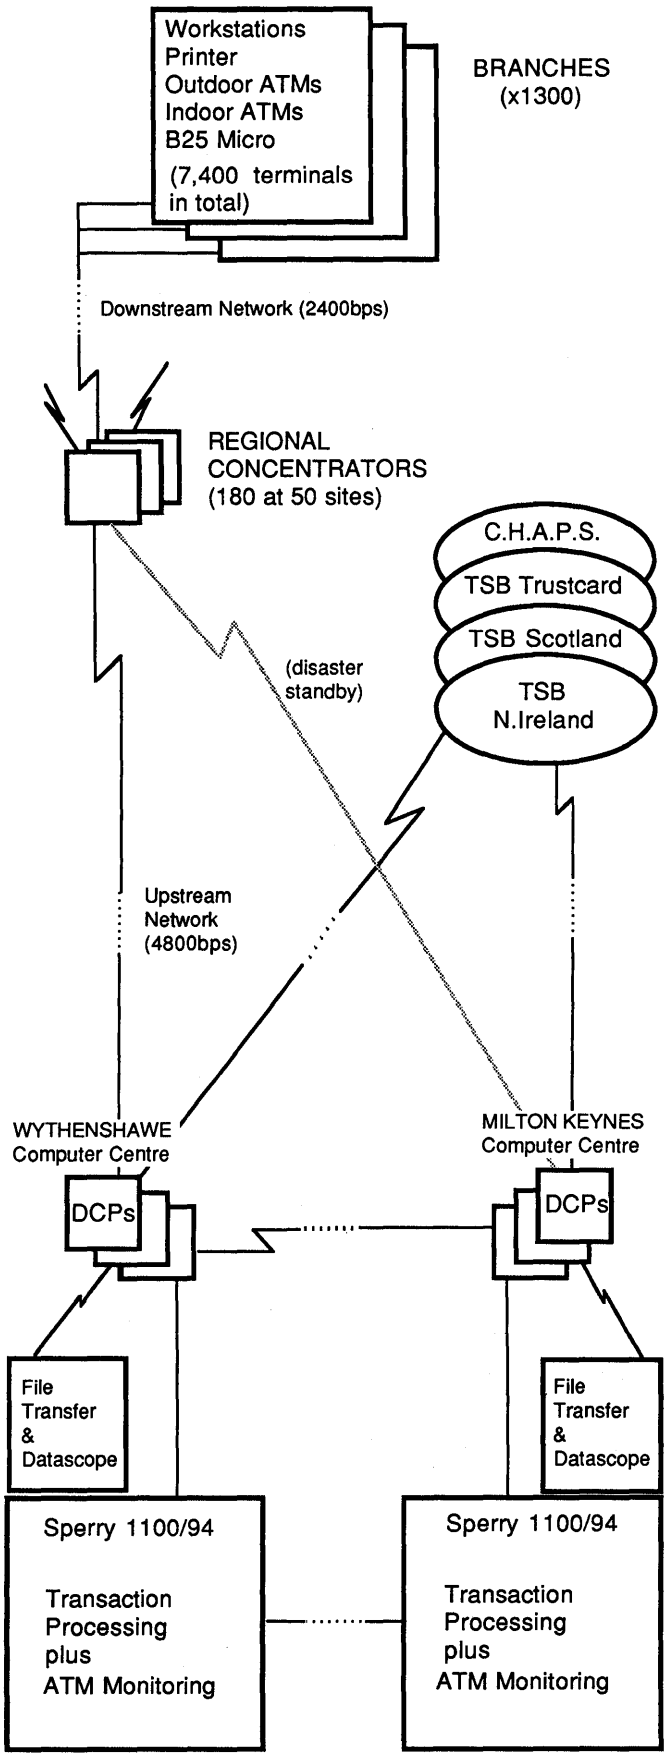

Figure 2. 1987 Network

3. . . . WITHOUT KNOWING IT!

Of course we knew about the escalating workload on the network, we could hardly fail to notice it!

The main measurement tool at our disposal was the mainframe. All transactions arriving at the mainframe are logged, and several programs have been developed to analyse the transaction traffic. For example, it is possible to plot the number of transactions originating from each downstream line of each concentrator during any chosen period.

Question: What other measurement tools were available? Answer: Not a lot.

The front end processors (Sperry DCP/40s) collected statistics about each upstream line, such as number of messages received/transmitted and number of characters received/transmitted. No tools were provided for retrieving, managing and analysing the statistics (no SAS on Sperry) so it was not until recently that they became of any use whatsoever.

We occasionally resorted to datascope line monitors to give us glimpses of the traffic. We even used stopwatches to time samples of transactions from a workstation or two (or relied on branch complaints). Such scraps of knowledge gained by very labour intensive means are so localised, geographically and in time, as to be quite unsatisfactory.

So we were left with significant unknowns about the activity in our network:

a) Little knowledge of the line loadings of each of the sixty upstream lines until the recent analysis of the DCP Statistics enabled estimates to be made.

b) Little knowledge of the contribution of the upstream to overall response time.

c) Little knowledge of the impact of initiating a file transfer from the computer centre to a concentrator, or of retrieving diagnostics from a concentrator.

d) Less knowledge of the behaviour of the 360 downstream lines, apart from number of transactions reaching the mainframe.

e) Very little knowlege of the impact of tellers requesting information, such as transaction logs or transaction menus, from the concentrators, or of how often they use these facilities.

f) Very little idea of the scale and impact of workstation program overlays being called up from the concentrator.

g) Very little idea of downstream line loadings, poll overheads and delays, retransmission overheads, contribution of downstream to overall response time, or contribution of concentrator to overall response time.

h) Very little idea of the impact on the network of the different transaction types.

i) Very little idea of how the network behaves during reports transmission.

j) Very little idea of the impact of autoteller health monitoring, or of CHAPS transactions, or of Mapper traffic.

k) Very little idea of the likely impact of adding additional devices to the poll trains, or of lengthening messages, or whatever, due to lack sufficient data to support modelling.

The knowledge that one doesn't have the knowledge tends to breed caution! Hence it has been policy to keep the workload fairly evenly balanced across the network, and to encourage sensible and economical use of the system.

Fortunately, the level of service provided to the users seems to have weathered most of the storms of change and growth described earlier.

"But for how much longer!" cry the capacity planners.

"But for how much longer!" cry the network administrators and controllers.

"But for how much longer!" would the users cry, if they knew what we know we don't know . . .

. . . and they probably will, because this year we are implementing service agreements between the user divisions and ourselves in Management Services.

4. FOCUSSING IN

You can't capacity plan the future if you don't know where you are now.

Similarly, you sign service agreements with your sponsors at your peril if your measurement and forecasting capability is suspect.

Clearly much, much more data on the network performance and workload was essential.

Perhaps the most obvious place for network measurement to be developed was in the concentrators, since they alone had a view of the otherwise quite separate upstream and downstream networks. If only they could have carried out round the clock recording of all measurements, for later transmission to, and analysis on, the mainframe! No chance. No suitable software was available from the supplier. Neither could any reasonably be developed in house given the limited capacity of the concentrators, the complexity of the work they are already carrying out, and the fact that all the development personnel skilled in Burroughs CMS/MPLII were fully stretched keeping up with the torrent of change.

The idea of an independent network monitoring system became increasingly attractive. Something that could be bought off the shelf, wheeled in, probed up to the lines, and left to collect data which it would then analyse and display in a wonderfully friendly format. Even better if it could then model proposed changes.

Just one or two problems.

Fine, if you've got a single level star network radiating from your centre, so that the monitor can be centrally sited. Unfortunately most of our lines (the downstream ones) are anywhere but near the computer centres.

Fine, if your protocol is 2780, 3270 or SNA. Un(?)fortunately not everywhere is an IBM site. Our protocols are Sperry HDLC (four-wire full-duplex but in Normal Resonse Mode) on the upstream, and Burroughs Poll/Select (half duplex) with Group Polling on the downstream; and they are, er-humm, slightly modified to give an extra high level control of the link, non standard multiblocking, . . .

Fine, if your transactions arrive in the same shape as when they left the terminal. Some of our transactions never get past the concentrators, and those that do are reformatted and addresses are stripped off so that only the concentrator software knows which device they came from.

Fine, if your traffic isn't cluttered up with unsolicited messages checking the wellbeing of autotellers, or carrying broadcasts to branches, or triggering special concentrator activity.

All-in-all, fine if your network is not TSB's!

With our shopping list of requirements and our purse we optimistically set off to the shops, only to find the shelves surprisingly bare. The supermarkets had no such departments, so we had to turn to the corner shops. Few of them had much to offer, even in plain, let alone fancy wrappers. Well there's nothing like having a short list to help you draw up a short-list.

It was clear that special protocol analysis would have to be developed by any potential supplier. It was also clear that to continuously monitor the entire network would require masses of such kit out near the downstream lines.

The short-list shortened itself further when one supplier decided it would only be worth doing the former (special development) if we committed to the latter (masses of kit).

Our purse was small; we were budgetted for only a modest system to start with. It would therefore have to be portable so that we could monitor the upstream and downstream lines for perhaps a week or two at one regional concentrator site before moving on to the next.

Eventually an order was placed with the only remaining supplier willing and able to meet our requirements at a price we could afford.

The system is a Dynatech PRISM capable of simultaneously monitoring twenty lines (upstream, downstream, or a mixture). It can measure at line, controller, or device level:

a) Response Time

- Average, Maximum, Std Deviation, No. over threshold

b) Host delay (ie upstream of monitoring point)

- Average, Maximum, Std Deviation, No. over threshold

c) Average Poll Delay

d) Number of Transactions

e) Percentage Line Utilisation

- Overall, Data, Protocol overhead, Inactive

f) Line Down Time

g) Line Idle Time

h) Retransmissions - Transmitted, Received

i) No. of Messages - Transmitted, Received

j) No. of Characters - Transmitted, Received

k) Total Number of Data Characters

l) Number of Polls

m) Number of No-Response-to-Polls

n) Number of Devices Active

Furthermore it claimed to be able to analyse the traffic down to individual transaction type. This was seen as one of the most important features of the system because of the wide variety of traffic, particularly on the downstream lines, and our lack of analysis of that traffic.

Once the PRISM system is fully operational it is hoped that

(i) the most threatened areas of the network can be analysed first, and a prognosis delivered before the service levels suffer.

(ii) it will serve as a "toe in the water" on network monitoring.

Thus we will start to form a clearer picture of the 1987 traffic on the 1980 network . . .

. . . <u>just as we are about to start replacing it with a 1988 network</u>!

5. <u>SUMMARY</u>

Piling the workload onto a finite capacity system of which one has only impaired vision is short sighted! We now see that . . . and hope the bifocals (ie upstream + downstream) we've bought will prevent us walking into anything unpleasant.

Ask yourselves: do YOU have an adequate picture of what is happening on YOUR network?

If not, how many years will pass before YOU identify in YOUR organisation THE NEED FOR A NETWORK MONITOR?

A Systematic Approach for Identifying Peak Periods

H. Pat Artis
Performance Associates, Inc.
Vienna, VA 22180

ABSTRACT: Basing capacity planning forecasts on peak periods is one of the most common approaches discussed by capacity planners. However, the identification of peak periods is not a trivial problem and is more often based on ***looking at the data*** rather than a defined procedure that can be automatically applied to large volumes of data. In this paper, we will examine statistical methods for identifying peak workload intervals based on a variety of measurements. The potential types of metrics that can be used for identifying peak periods include measurements of load, utilization, and service level.

1.0 Introduction

One of the most common problems presented to the performance analyst is the selection of peak intervals for modeling and/or workload forecasting.[1] However, the identification of these peak periods, if they do not occur at a regular time each day, is more of an art rather than a procedural approach that can easily be applied to large volumes of data and/or tuned to achieve more desirable results. As such, peak periods seem to be more illusionary rather than measurable and definable periods that do not require significant insight into the system's workload on behalf of the analyst to identify.

Perhaps the most common approach to the identification of peak intervals is the selection of time periods during which CPU utilization is very high. Historically, there have been two primary motivations for the use of CPU utilization to identify potential peak periods. They are:

- CPU utilization can be easily measured in a reliable manner,
- since the CPU is the most expensive single resource, management has historically viewed CPU utilization as a primary indicator of system capacity.

Although reasonable, these motivations are subject to question in today's environment. First, MVS/XA attempts to recruit (implemented by target MPL modifications made by the SRM) low priority (i.e., non-critical) work during idle periods in an attempt to maximize CPU utilization. However, the recruited workloads would be rapidly shed by the SRM in the event that some critical workload were to demand resources. Moreover, as the fraction of our workloads represented by on-line systems continues to increase, service levels become a dominate concern over CPU utilization.

Although one might argue that using service level values for the identification of peak periods offers a solution to the problem, arguments similar to those that were used to question focusing on CPU utilization can easily be hypothesized. Thus, any approach to the identification of peak periods must be multi-dimensional in nature, where weights can be assigned to various metrics in relation to the importance that they play in allowing the system to provide essential services and meet stated service objectives. Such multi-dimensional metrics used are called ***objective functions.*** Objective functions are most commonly used by optimization procedures to allow their searching algorithms to differentiate between alternative cases.

Defining an objective function for the identification of peak periods presents a number of problems. They include:

- the varying range of values over which each of the metrics is defined,
- the selection of the metrics used to define the objective function.

Each of these problems will be discussed in the following section.

2.0 Defining Objective Functions

The first problem presented to the analyst attempting to define a multi-dimensional objective function are the broad, and differing, ranges of values over which each of the potential metrics are defined. Perhaps the simplest way to address the problem presented by these varying ranges of values is scaling. For the purposes of this study, the author suggests that Z-statistic scaling be used to normalize each of the metrics. To Z-scale an observation, one simply subtracts the mean and divides by the standard deviation calculated for the metric. Z-scaling maps the vast majority of all observations over the range of -3.5 to +3.5, where a scaled value of zero implies that the observation was identical to the mean. Positive values are indicative of observations larger than the mean and negative values are indicative of observations smaller than the mean.

Once the potential metrics have been scaled, the analyst is presented with the question of which metrics should be included in objective function and what weights, if any, should be applied to the individual metrics. While the selection of the metrics is dependent on both the analyst's judgment and management's objectives for a specific system, potential metrics fall into three broad categories. They are:

- utilizations and other measures that are indicative of the hardware or the operating system's activities,
- indicators of load such as job and/or transaction counts,
- service level indicators such as response or turn around times.

In general, the scaled metrics describing any of these types of measurements can simply be added or averaged to yield an objective function value. However, in some cases, weights can be applied to the specific metrics to emphasize or de-emphasize their importance in the calculation of the objective function.

Although the use of weights is usually unattractive, there are specific cases where weights can be very useful. For example, consider the case of two TSO systems, a system for data center personnel (i.e., internal) and a second system for paying customers (i.e., external), sharing the same CPU. Although the service levels for the internal TSO system are of some concern, the revenue producing external system is management's primary concern. As such, applying a weight of 1/2 or 1/3 to the internal service metric would express its relative importance to the overall performance of the data center.

3.0 Case Study

To illustrate the approach to identification of peak periods discussed above, the technique was used to analyze hourly data collected for a CICS workload operating in an MVS/XA environment. Based on Detich's and Simpson's papers [2,3] that discussed the collection of key measurements to model CICS transaction response time, the following metrics were selected to characterize the hourly observations:

CPU Utilization: the percent of the CPU resource being consumed by all of the system's workloads. As the CPU utilization increases, it is more likely that a CICS transaction will encounter queueing delays as it competes for CPU resource,

Pages per Second: the load being carried by the auxiliary storage management system. Because of CICS's well known sensitivity to paging, this metric is considered to be a leading indicator of overall CICS performance,

Average Page Delay Time: the delay, in milli-seconds, experienced by a transaction when a page fault occurs,

Transactions: the number of CICS transactions processed during the hour,

Trivial Response: the average internal response time for trivial (i.e., transactions with low CPU and I/O requirements) CICS transactions.

The data collected for the CICS system during one prime shift interval is shown in **Figure 1.**

Hour	% CPU	Page/Sec	Avg PDT	Tran(K)	Trv Resp
8	68	113	4.5	53	0.41
9	77	140	4.9	137	0.65
10	95	241	5.7	187	0.87
11	94	237	6.3	181	0.92
12	72	155	4.6	71	0.49
13	86	201	5.1	172	0.80
14	97	229	5.2	184	0.85
15	96	233	6.1	175	0.91
16	87	198	5.1	162	0.75

Figure 1. Hourly System Measurements

A cursory examination of the data based on CPU utilization reveals that hour 14 might be the peak interval based on CPU utilization. However, other key indicators like average page delay time, CPU utilization, and response time do not indicate that the full resources of the system were stressed during the period. Using the approach discussed in the prior section, the means and standard deviation values were calculated for each of the metrics. These results are shown in **Figure 2.**

Hour	% CPU	Page/Sec	Avg PDT	Tran(K)	Trv Resp
8	68	113	4.5	53	0.41
9	77	140	4.9	137	0.65
10	95	241	5.7	187	0.87
11	94	237	6.3	181	0.92
12	72	155	4.6	71	0.49
13	86	201	5.1	172	0.80
14	97	229	5.2	184	0.85
15	96	233	6.1	175	0.91
16	87	198	5.1	162	0.75
STD	10.37	44.56	0.59	47.69	0.17
MEAN	85.78	194.11	5.28	146.89	0.74

Figure 2. Mean and Standard Deviation Calculations

By using these values to Z-scale the individual hourly observations, each of the potential contributing metrics can be scaled into a common range.

Using the scaled values, three different objective functions were evaluated. They were:

- an objective function based on CPU utilization, pages per second, average page delay, total transactions, and trivial response time,
- a four value objective function based on CPU utilization, average page delay, total transactions, and trivial response time,
- a three value objective function based on CPU utilization, total transactions, and trivial response time,

Each of these objective functions are discussed in the following sections.

3.1 Five Value Objective Function

The first objective function was defined as the un-weighted average of the Z-statistics of the five metrics discussed in the prior section. The objective function was calculated:

$$\text{Obj Fun} = \frac{\text{Z-CPU} + \text{Z-Page} + \text{Z-PDT} + \text{Z-Tran} + \text{Z-Resp}}{5}$$

The result of this objective function calculation is shown in **Figure 3.** The peak hour is denoted by the > and < symbols.

Hour	% CPU	Page/Sec	Avg PDT	Tran(K)	Trv Resp	
8	68	113	4.5	53	0.41	
9	77	140	4.9	137	0.65	
10	95	241	5.7	187	0.87	
>11	94	237	6.3	181	0.92<	
12	72	155	4.6	71	0.49	
13	86	201	5.1	172	0.80	
14	97	229	5.2	184	0.85	
15	96	233	6.1	175	0.91	
16	87	198	5.1	162	0.75	
STD	10.37	44.56	0.59	47.69	0.17	
MEAN	85.78	194.11	5.28	146.89	0.74	
						OBJ FUN
8	-1.71	-1.82	-1.31	-1.97	-1.89	-1.74
9	-0.85	-1.21	-0.64	-0.21	-0.51	-0.68
10	0.89	1.05	0.71	0.84	0.75	0.85
11	0.79	0.96	1.72	0.72	1.04	1.05
12	-1.33	-0.88	-1.14	-1.59	-1.43	-1.27
13	0.02	0.15	-0.30	0.53	0.35	0.15
14	1.08	0.78	-0.13	0.78	0.64	0.63
15	0.99	0.87	1.38	0.59	0.98	0.96
16	0.12	0.09	-0.30	0.32	0.06	0.06

Figure 3. Five Metric Objective Function

Based on this objective function, the peak interval occurs during hour 11, when CPU was only moderately loaded. Simply stated, the contribution of CPU utilization to the objective function was not an over riding concern when service related factors (i.e., page rate, average PDT, and response time) were factored into the calculation.

This objective function illustrates one potential concern of which the analyst must be aware. The use of two or more related metrics may place an undesired (and perhaps unanticipated) weight on one of the systems resources. In the five metric objective function introduced above, paging rate and average page delay are likely to illustrate a high correlation. To investigate this potential effect, a second objective function was evaluated using only one of the paging metrics.

3.2 Four Value Objective Function

The second objective function was defined as the un-weighted average of the Z-statistics of the four metrics. For this case, paging rate was removed from the objective function discussed in the prior section. The objective function was calculated:

$$\text{Obj Fun} = \frac{\text{Z-CPU} + \text{Z-PDT} + \text{Z-Tran} + \text{Z-Resp}}{4}$$

The result of this objective function calculation is shown in **Figure 4.** The peak hour is denoted by the > and < symbols.

Hour	% CPU	Page/Sec	Avg PDT	Tran(K)	Trv Resp	
8	68	113	4.5	53	0.41	
9	77	140	4.9	137	0.65	
10	95	241	5.7	187	0.87	
>11	94	237	6.3	181	0.92<	
12	72	155	4.6	71	0.49	
13	86	201	5.1	172	0.80	
14	97	229	5.2	184	0.85

Figure 4. Four Metric Objective Function

As can be seen in the figure, the four metric objective function yields results similar to those developed in the prior section. That is, the peak interval still is identified as hour 11 in the study.

As a final step, an even simpler objective function was evaluated that excluded all virtual memory metrics. As a broad guideline, the author would recommend that the analyst attempt to choose the simplest objective function that incorporates their key measures of load, utilization, and response. The use of a minimum number of metrics allows the analyst to more easily anticipate how the objective function will behave over a broad range of values. However, the selection of these metrics is dependent on the specific characteristics of the installation.

3.3 Three Value Objective Function

The third objective function was defined as the un-weighted average of the Z-statistics of CPU utilization, transaction volume, and response time. The objective function was calculated:

$$\text{Obj Fun} = \frac{\text{Z-CPU} + \text{Z-Tran} + \text{Z-Resp}}{3}$$

The result of this objective function calculation is shown in **Figure 5.** The peak hour is denoted by the > and < symbols.

Figure 5. Three Metric Objective Function

Using the three metric objective function identified hour 15 as the peak interval for the study. Once again, hour 14 during which the highest CPU utilization occurred was not selected by the algorithm.

4.0 Remarks

In this paper, an objective function approach for identifying peak intervals in measurement data has been discussed. While the analyst must still select the metrics and weights to be used in the definition of the objective function, it provides a structured approach to the identification of peak periods in large volumes of measurement data.

WORKLOAD-ORIENTED PERFORMANCE ANALYSIS IN MVS

Stephen L. Samson
!Candle® Corporation

ABSTRACT

The analysis of acute performance problems in large multiprogramming operating systems such as IBM's MVS has evolved from resource-based views to those centered on the workload in trouble. A recently-implemented technique builds on the workload view, looking back at other workloads in the system to pinpoint sources of resource contention. The performance analyst as detective is now able to depend on eyewitness testimony rather than on circumstantial evidence. In this paper, we will examine the various techniques and their use when responding to performance problems.

INTRODUCTION

Acute performance problems in MVS systems have been investigated from numerous points of view. If we had perfect insight into workloads and their relationship to one another and to the operating system, we'd see that when a workload fails to meet its service objectives its access to resources is usually impeded by some other workload. Rarely is it true that the programs supporting key workloads are so flawed in design that they continually incur self-contention, nor are they so hungry for resources that they simply cannot get enough CPU, storage, or data to meet their service targets. Although many counterexamples do exist, a single workload usually runs well all alone.

Unanticipated and severe performance problems on machines with well-understood complex workloads can hardly ever be capacity problems. Unfortunately, we often look first at resource data also used by capacity planners just because it is available. Thus as we examine the state of the art in analyzing, and devising solutions for, acute performance problems, we find that we are almost always looking at the wrong data. If we want to know why "CICS has gone silly," do we look at the system to discover which other workload has the CPU when CICS wants it? Of course not! We might be able to discover which workload is receiving the most CPU service in the current time frame and, in the interest of doing "something...anything!" we cancel a poor innocent batch job running at such a low dispatching priority it couldn't possibly be in contention with CICS. At the same time, we miss the real culprit: JES2 is busy dumping a 40 megabyte file through a channel-to-channel adapter to another system. We cleverly offloaded printing, only to cause JES to dump data into an efficient bottomless pit. (All the CPU time attributable to JES did not show up because it builds a very efficient, tight loop around EXCPs. The path through I/O completion code is much longer than the path through JES.)

In this paper and its companion presentation, we'll examine the awakening of an installation to the possibility of MVS performance problems and consider several approaches to solving them. Of necessity, the last solution presented will introduce a new approach now implemented exclusively in a product of Candle Corporation. We mention this fact at the outset to prepare the reader for what may appear to be the presentation of product information. This is not the purpose of the examples in the presentation; they are there only as a concrete demonstration of the value of directly observed workload contention. Product identification has been removed from the examples.

This paper roughly parallels the presentation. Cross-references are not included in the text, but the visuals are attached as an appendix.

EARLY STAGES OF A NEW MVS SYSTEM

Bringing up a new system

As a new MVS system is installed, say as a twin to an existing system to deal with workload growth,

©Copyright Candle Corporation 1987. Permission is granted to The Computer Measurement Group, Inc. to publish this paper for the exclusive use of its members. All other rights reserved.

performance is not a consideration at first. There is so much work for the system programmer[1] to do:

- Ensure that all of the operating system is installed at a consistent level. Our definition of the operating system might encompass BCP, DFP, and JES.
- Verify the maintenance level of the operating system and add selected fixes known to be needed.
- Add the next layer of vendor-supplied "system" code to the operating system core. At this point, there is not yet a meaningful workload to exercise the system.
- Verify consistent maintenance levels and rectify any detected conflicts.
- Verify IPL and basic function.
- Add vendor-supplied subsystem packages such as CICS.
- Verify consistent maintenance levels and rectify any detected conflicts.
- Verify IPL and basic function.
- Add exits and local modifications to the operating environment.
- Verify consistent maintenance levels and rectify any detected conflicts.
- Verify IPL and basic function.
- Add extensions to subsystems (other vendors, home-grown).
- Verify IPL and basic function.
- Install or re-install application packages.
- Verify IPL and basic function.
- Prepare customized PARMLIB and other parameter files to support local standards.
- Verify IPL and basic function.
- Apply a test workload and verify functional soundness.
- Gradually bring on more comprehensive functional test workloads.
- Apply a "stress test" workload (usually synthetic) and verify that performance is satisfactory at or beyond planned capacity.
- Turn the system over to production.

Even the penultimate step in this long process, the "stress test," is often incapable of detecting incipient performance problems. The stress workload is difficult to structure to represent the dynamic interactions of real workloads; it is usually deemed adequate if it can verify gross capacity. Thus the real workload is applied to the system with little more than a warm feeling that function has been verified, and that the hardware configuration *should* be able to do the job. It should hardly be a surprise, then, when performance anomalies develop.

Initial production operation

Few new systems come into production fully loaded, so it is likely that few performance problems will appear early in a system's life. Following the analysis for CPU queuing employed by Mr. Siebo Friesenborg of IBM, as well as by my colleague at Candle, Mr. Steven Hackenberg, we note that the probability of some CPU queuing increases rapidly for a workload when the percentage of CPU utilization at higher dispatching priorities exceeds 50 percent. Suppose that CICS is the "loved one" (in IBM's vernacular) of our system and that it takes up 20 percent of the CPU capacity. If JES, TSO, and system activities at higher priorities than CICS take up 35 percent, CICS is at the point of beginning to sustain measurable CPU delay, reflected internally as "wait on dispatch." Note that the CPU may be only 55 percent busy.

If we now add more workload to this system, we will affect CICS's performance. If the added workload is low-priority batch, the only activity in contention with CICS for the CPU is the increase in JES consequent to batch SPOOL activity, as well as some increase in IOS due to the batch jobs' I/O. We might load the system at close to 100 percent CPU busy without appreciably increasing CICS's CPU delay.

If on the other hand we choose poorly, we can hurt CICS significantly with far less of an increase in gross utilization. If TSO first period is higher in dispatching priority than CICS, an additional 20 percent utilization due to trivial TSO will more than double the CICS CPU delay, even though the CPU is still "only" 75 percent busy. Figure 1 shows that for the case cited, elongation due to CPU contention increases from about 80 percent to about 220 percent. A CICS transaction requiring 200 milliseconds of CPU time will wait about 160 milliseconds for CPU service before the system load is increased. After the increase of TSO usage, the delay is about 440 milliseconds.

This disproportionate increase in delay due to an increase in utilization applies to other resources as well. Paging delay is insignificant until the available frame queue is depleted to the point that page stealing will take away vital frames. I/O delay is no problem until a buildup of device utilization starts to cause device queuing, or a rise in path utilization leads to measurable RPS miss. (At that point, the increased device utilization consequent to RPS miss also tends to produce device queuing delay.)

---

[1] We recognize that "performance analyst" and "system programmer" usually refer to the same person, and that only rarely is that person known as "capacity planner" as well.

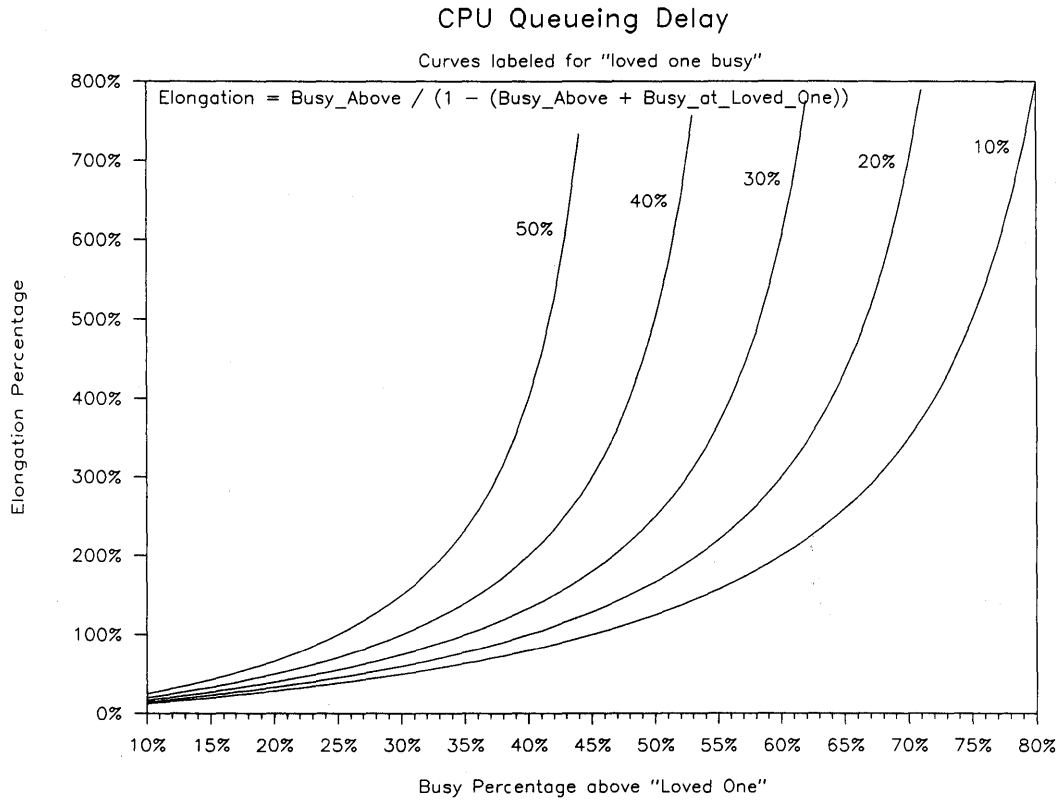

Figure 1. CPU delay family of curves

As we create models for these phenomena and analyze their outputs, we often make unwarranted assumptions of randomness. We move deftly from a discussion of CPU utilizations to one of expected CPU queuing delay, transforming utilizations into probabilities as if they were equivalent. In many cases, they are. We may assume reasonably that TSO and CICS are independent. But what of JES or a file server to CICS? If demand at dispatching priority above that of the "loved one" is synchronous with activity in the "loved one," random models are far too optimistic, and delay may be virtually certain, even at modest CPU utilization.

Initial overt problems

We might picture the system happily running with no perceived performance problems while the subclinical conditions grow, waiting to burst forth as full-fledged incidents. We define an *incident* as a detected failure to meet some service objective. With luck, the data center staff may be the first to detect an incident. This rarely is the case. The system may, after a few months of production operation, have no comfortable margin of CPU or storage or I/O capacity, and the first routine fluctuation in demand that goes beyond a critical threshold will trigger an incident.

Loss of innocence

Some time after the support staff has become convinced that they can do no wrong, the first messy incident will take place. The MIS Director may be enamoured of his Resource Scheduling System and its flashy color displays. He is demonstrating it for the CFO's budget planning meeting. Just as he prepares to make his climactic point, a batch job is being freed from allocation recovery. The operator names the device containing the Resource Scheduling System, because it's private, non-production, not familiar, and it has four hundred cylinders free. (A quad of scratch volumes is down for concurrent preventive maintenance, causing the allocation recovery event.) The first step of the batch job restores an archived data set. The tape is mounted just as the MIS Director presses **ENTER**. The very efficient restore program creates ***long*** channel programs. Even with priority I/O queuing, the ten I/Os needed serially by the MIS Director are interspersed with hundreds of I/Os for the restore....

In the aftermath of the "demo debacle," management reacts as it must; committees are formed, recommendations are made, and tools are acquired (or just put in use if they hadn't been.) Other less acute incidents are evaluated, and the realization grows that service is not all that it could be. Based on the input of

hardware vendors and out-of-town experts, a plan is devised and put into effect.

AN INITIAL PLAN—ROTS

In the absence of any solid information about contention or degradation (execution state analysis), it is difficult to see how an initial plan could be based on anything but rules of thumb ("ROTs"). The theory of this approach to performance management is simple. If you measure what you can when the system is running well and repeat the measurement over time, accumulating a data base of measurements, you can infer the normal resource utilization pattern of the system, and even infer a set of normal operational limits. You confirm that, when the system is running poorly, one or more of these measurable values is outside of the limits.

You may also choose to adopt ROTs reflecting received wisdom, straight from the out-of-town expert.

Once you have demonstrated the correlation between poor performance and operation outside of some limits, you can begin establishing a series of thresholds that may be automatically applied against the system by a product capable of performing exception analysis, such as Candle's OMEGAMON®/MVS. Whenever a threshold is tripped, an exception message is presented to the operator, and corrective action can be initiated.

Taking action with ROTs-based performance management

Using ROTs is a utilization-based approach to performance management. An exception in such a methodology is an observed resource utilization level that violates a threshold. Once an exception is detected, corrective action is based on the same kind of information. The goal is to change the utilization level of the resource and return to the normal operational range. So far, so good.

The difficulty in ROTs-based performance management appears at this point. How does one determine the appropriate action? There are numerous sources of advice on how to proceed in this situation, but it is too easy to fall into the trap of indiscriminate load shedding. If a subsystem workload like CICS or IMS is the subject of response time complaints and an exception for "excessive CPU utilization" is displayed, the natural reaction is to cancel whichever batch job is using the most CPU resource at the time. We know that cancelling a job that will be replaced by the next job on the queue will not work in the long run, but isn't it satisfying to do *something?*

More considered approaches are based on longer-term data and may lead to tuning atrocities such as imposing restrictive constraints on batch domains, activating response time objectives (RTO) on TSO first period, adding a delay domain in TSO, and cutting back to a deliberately inadequate number of initiators. All these actions are consequences of utilization-based performance management and either second-guess or contradict MVS's workload management mechanisms.

The pessimistic and inherently inflexible state of mind engendered by a dependence on ROTs also may lead to ill-considered hardware procurement. Many system configurations become distorted and unbalanced by the addition of unnecessary fast paging devices or even CPU upgrades in response to a perceived resource shortage, solely the result of exceeding an arbitrary threshold and concluding that a resource is exhausted.

Drawbacks of ROTs-based performance management

It might appear that the type of actions that ROTs-based performance management leads to are enough of a reason to reject the approach. Several additional considerations add greater force to the rejection:

- Resource exceptions have little or no relevance to service levels.
- Service exceptions are poorly correlated with resource measurements.
- ROTs are based of necessity on wisdom of the past.
  - Obsolete models and legends
  - Obsolete workloads and structures
  - Major lag when systems change
- Cause and effect are confused
- ROTs attempt to level special cases

A LOGICAL TUNING APPROACH

Several years ago, as MVS production systems got to be of crucial importance to the enterprises in which they were installed, more effective performance management disciplines became necessary and started to appear. These new methods were built on developments that occurred in that time frame:

- Service level targets, agreements, and contracts appeared and matured.
- Measurement tools, supporting programs, and data-base systems capable of tracking the performance data needed to administer service-level agreements came into widespread use.
- Other measurement tools capable of revealing a detailed breakdown of elapsed time or response

time became available. With such tools, the detection of a service anomaly can lead to rapid discovery of specific bottlenecks.

- The basic mechanisms of MVS were refined and improved, and many impediments to system growth and flexible workload management were overcome. This process continues with the MVS/XA releases that have appeared recently.

The net effect of these developments made a more logical approach to MVS performance management possible. The new methodology was superior to a purely utilization-based approach. The stepwise approach, called the "logical tuning approach" by Candle Corporation, may be executed in real time for acute performance problems, or after the fact for problems that are detected over a longer time interval. It consists of the following elements:

1. Is there a service-level problem? If not, return to routine monitoring.

2. Determine the nature of the bottleneck responsible for the service-level problem. ("Where does it hurt?") Use Degradation Analysis (also known as execution-state analysis or response-time-component analysis) to rank the execution states of the workload failing to meet its target.

3. Select the most prevalent tunable execution state (*e. g.* "waiting for CPU") and identify the cause of the contention or resource exhaustion. The cause will usually be another workload or, perhaps, an MVS parameter that can be adjusted so that the affected workload will be more likely to obtain its required resources with reduced contention. Execution state analysis will also reveal competing workloads in many cases, such as which other performance group is using a device needed by the "loved one."

4. Take appropriate action. Examples include setting a new IPS to improve dispatching priority or storage isolation, swapping out or requeuing and cancelling a job causing I/O contention, or PAGEADDing an extra page data set to cope with a temporary increase in paging activity.

5. Finally, return to routine monitoring of service targets.

Note that "routine monitoring" with degradation-oriented tools can lead to an appreciation of the normal profile of execution states for each key workload. Tracking such profiles over time with emphasis on delay states can provide valuable early warning of impending overload incidents. Such tracking is a valuable adjunct to conventional capacity projection methods.

Pros and cons of the logical tuning approach

The logical tuning (or degradation-based) approach is simpler to use and more precise than a resource-based approach leaning on resource ROTs. The focus is correctly on the workload in trouble, and initial investigation leads rapidly to the most promising resource for adjustment of demand or tuning effort. If the relief chosen is a tuning effort with respect to the workload not meeting its service targets, this method can lead to appropriate corrective action quickly and accurately.

The degradation-based approach is less successful when tuning of the ailing workload is not an effective response. In the case of acute contention for a resource by competing workloads of greater or equal importance than the afflicted one, the question that needs to be answered is not "Where do I hurt?" so much as "Who's hurting me?" In such a case, all that the degradation-based approach can do is tell who else is using the scarce resource, and we are led again into the error of confusing concurrent utilization with contention.

WORKLOAD-ORIENTED PERFORMANCE MANAGEMENT

What's needed to solve the acute contention problem is a way of determining, from the viewpoint of a workload of interest, which other ***workload*** is keeping "me" from getting the resources "I" need. This is ***not*** the same as finding out who else is using the resource in the same time frame I am. If we imagine a sampling monitor, the basic cycle of operation would not be to classify execution states of address spaces, but to look for address spaces that require service but are not currently receiving it. Such address spaces may be on the dispatcher's "ready" queue, waiting for page fault resolution, waiting for swap-in, queued on a UCB for a busy device, and so forth. Once such address spaces are identified, the analysis goes on to determine which other address space is currently using the needed resource.

Impact analysis

Candle Corporation has recently introduced the first product embodying this methodology, called *Impact Analysis*. It is in a CICS product, but the methodology is certain to appear in other environments as well. Once a failure to meet service objectives is known or suspected, a few minutes worth of Impact Analysis data collection can reveal which other workload is preventing the workload of interest, CICS in this case, from meeting its service objectives.

Contrast with older methods

Impact Analysis (IA) is quick and efficient. If the dispatching priority of the collector is high enough, occurrences of disproportionate contention such as those caused by synchronous invocation of server code can be revealed. As in Degradation Analysis, the data shown by Impact Analysis needs to be consulted in the context of a service level exception if conclusions drawn about indicated contention are to generate action. An impact display or impact profile for a workload behaving normally may show contention, even high values of contention. Such a display simply reflects the fact that queues exist in MVS and that some delay is the price for the considerable benefits of multiprogramming and shared use of system resources.

When synchronous contention at higher dispatching priority is seen to be a significant cause of delay, we become able to evaluate hardware configuration and software architecture choices more effectively. The effect of such contention may be minimized better in a multiprocessor than in a uniprocessor, and in a muli-task structure rather than in a serialized software architecture.

Properly drawn service-level agreements acknowledge the existence of delay and do not commit the service provider to strive for theoretical minimum response times, but for attainable response times that meet the business needs of the users.

CONCLUSION

There has been an evolution in methods to deal with acute performance problems in MVS. The earliest approach based on measured data rather than on intuition used resource data only, and exception detection was based on violation of resource-based rules of thumb (ROTs). Corrective action (if possible in real time at all) was usually based on ranking the users of the constrained resource and taking some drastic action against the most prominent user not known to be "important."

The second stage of the evolution became posssible with tools performing Degradation Analysis (Execution State Analysis) and with the rise of Service-Level Agreements. In the degradation-based methodology, exception detection is based on failure to achieve service level targets, and corrective action is based on information gathered over time by a degradation analysis collector. This methodology focuses more rapidly on specific problem causes than did the earlier one, but corrective action is still largely resource-based. Resource-based corrective action is usually effective if it is a positive action to improve access of the workload in trouble to the resources it needs. Changing storage isolation or dispatching priority are examples of such effective positive actions. Negative actions against apparently competing workloads, however, are almost as likely to be misdirected or ineffectual in this methodology as they are in a purely resource-based system.

The most recent stage in the evolution is marked by the introduction of Impact Analysis. A problem-solving methodology based on Impact Analysis continues to be dependent on service level analysis for detecting exceptions. Impact Analysis for problem source analysis and for response selection captures the essence of "speed of use," leading rapidly both to correct identification of contending workloads and to decisive corrective action.

ON THE OPTIMIZATION OF MEMORY IN LARGE INTERACTIVE ENVIRONMENTS

Anthony G. Mungal.

ABSTRACT

Large interactive environments can put a significant demand on the memory resources of a processor. Memory is an expensive finite resource; proper exploitation of which can contribute to enhanced workloads and overall greater throughput. In environments where cost is of little concern, it is advantageous to configure the processor with its full complement of memory. That necessarily implies that most, if not all, workloads that compose the multi-programming level will suffer fewer page faults, and hence, experience their maximum throughput (to the constraints of the CPU itself and the I/O subsystem).

In other environments, where the economic benefits of additional memory are not as easily felt, controlling the amount of logical swap incurred by the interactive system, can result in an effective tuning of the memory resources, such that, the productivity associated with low and consistent response times remain at an economical advantage.

This paper discusses a technique whereby main memory is "tuned" effectively to achieve the best compromise between job throughput, response times and cost; it employs a technique of off-loading a certain amount of logical swapping, allowing more "free" memory to exist. Indicators of memory contention are examined and interpreted in order to evaluate the best cost/performance alternative. This analysis (which utilizes actual customer data) will answer the question : How much memory is optimal?

The existence of more free memory naturally results in a lowering of the page fault rate, and thus, a more productive system can be realized.

INTRODUCTION

The trend of data processing environments is related to many concurrent evolutions of various pieces of hardware. One can look at the trends of at least the following pieces of hardware: the processor, memory, and the I/O subsystems. While those trends continue, the capacity planner struggles with the decisions and justifications of at least the following: the size and capacity of the current and/or future processor(s), the size of main memory, the appropriate number of channels, the number of users, the working set size of the user, and of course, the associated response times. In trying to evaluate the usage of memory within these sprawling interactive environments, one must look at the various interactions of many variables.

A methodology exists for optimizing main memory through the careful selection, interpretation and subsequent monitoring of certain memory indicators; those indicators are discussed within the context of an MVS/TSO environment. For TSO environments, logical swapping is commonly utilized to maintain low, consistent response times. That may be to the detriment of other workloads within that environment.

This paper discusses the necessary indicators of memory contention, and suggests proven alternative methods for optimizing the useage of memory. Much reference is made to an assortment of large environments which indulged in the same or similar analyses; data from those environments is included. The latter portion of this paper deals with the cost/performance or economic issues surrounding the deployment of memory on similar processors, and hence, forms the basis for evaluating the effectiveness of the capacity planning decisions involved.

WORKING SET DEFINITION

The definition of the working set as it applies to a job or interactive user has received increased attention over the years. Denning [11] proposed its concept many years ago. Garay et al [7] formalizes a rather useful definition of the working set as it applies to an interactive user; it is summarized below:

Let the set of addresses be

$X = \{x1, x2, \ldots, xn\}$. Denote a

reference string of length k as a sequence r, such that

$r = \{r1, r2, \ldots, rk\}$ and each member of r

belongs to X. The duration of reference is denoted T, a positive integer such that

$T = t1 - t2$ for all $t1 > t2$.

The working set during T thus becomes a reference string W(T), such that

$$W(T) = \{r1(t), r2(t), \ldots, rk(t)\}$$

and $t \in [t1, t2]$, thus providing the set of all referenced pages during the interval t. Now W(i) can denote the working set of the ith user during execution. The average working set size of all users becomes simply,

$AW = W(1) + W(2) + \ldots + W(n)$ or

$$\sum_{i}^{n} W(i) \qquad n > i$$

The cardinality of the working set (working set size) can be denoted

$$s(i) = \lceil W(i) \rceil$$

s(i) is further subdivided into swap sets (each of 12 pages), forming disjoint subsets of W(i), so that swapping can handle the individual subsets

$$S1(i), S2(i), \ldots, Sm(i)$$

where m is the number of swap sets. Note the potential for Sm(i) i.e. the last swap set, to be less than 12 pages.

The above terminology will prove useful for certain situations later.

TSO ISSUES

THE TSO USER

In looking specifically at the TSO environment, it is useful to trend the address space size of the user as it evolved through various releases of MVS. For example, observations indicate that the average TSO user increased in size by at least fifty percent in going from MVS/SP to MVS/XA. Also, the XA operating system itself allows the user to exploit a much larger address space (thirty one bit addressing), thereby allowing him a two gigabyte address space as an operating domain. Those two factors, taken by themselves or together, clearly has some significant impact on the paging and swapping loads observed within some systems.

The typical TSO user has had an increase in his working set size, which in turn reflects the potential for an increased amount of demand paging (page faults) in order to achieve transaction completion. The increase in demand paging per transaction per user has resulted in dramatically higher page rates for the overall paging subsystem; this has resulted in the adaptation of very robust paging and swapping subsystems. Clearly, the need for page and swap subsystems that can handle high page rates and provide low, consistent response times depends on the size of the processor, the number of users, the number of transactions, and of course, the amount of real and expanded storage (memory).

TSO RESPONSE COMPONENT ANALYSIS

An examination of the components of TSO response times reveals various entities such as: I/O time, CPU time, page-in time, and swap-in time. Beretvas [2] details some calculations that enable a post facto component analysis for TSO. In the majority of environments studied, the major contributor to degraded response times was swap-in delay. Swap-in delay is the time taken to bring a user from auxiliary storage (page or swap datasets) to main storage; it can also be measured/calculated for users brought in from expanded storage (in the microsecond range). Swap-in delay is easily calculated from Resource Management Facility (RMF) data, and is detailed below:

swap-in delay = (average absorption rate
average transaction service rate) *
average time of ended transaction

The correction term that may be applied to the above swap-in delay value for situations that employ a large amount of logical swapping is a multiplier of the form 1/(1 - %logical swap).

It should be noted that the TSO response time parameter (RTO) can be used to limit the service given to TSO. This is accomplished by the SRM delaying the TSO transaction after the command or other terminal input but before swap in occurs; this can impact swap-in delay values and the user is urged to discount swap-in delay calculations accordingly. A good discussion of RTO can be found in [12].

SWAP-IN DELAY AND PATH CONCURRENCY

It is desirable to maintain low swap-in delay in order to experience low, consistent response times. Many swap subsystems (especially those on rotating disk) will not ascribe to the property of low, consistent service times under load, and hence, are unable to guarantee low and consistent response times; the exception to this is the solid state disk. This solid state subsystem is discussed by Moore [12], Cheung [5], and Mungal [8]. In fact, due to the inherent sensitivity of rotating disk to I/O load, rotating disk will be a dissappointment when one needs it the most (high quantity of I/O needs to be done).

As the TSO user increases in size (region), the greater the probability that the working set size s(i) will increase, thereby leading to a larger value for "m", the number of swap sets. The swap operation becomes bigger, thereby requiring more concurrency denoted "c". That concurrency is needed along swap paths, controllers, and actuators, and can be denoted "m/c"; for DASD swap subsystems, it is optimal for c to be at least equal to m; for solid state swap subsystems, it is often sufficient for c to be not less than two, and not exceeding m/2 (i.e. $2 \leqslant c \leqslant m/2$). Of course, regardless of the type of swap subsystem, swapping becomes optimized for values of c equal to m (c=m). The major benefit of maximum concurrency is the reduction of swap-in delay.

SWAP-IN DELAY AND RESPONSE TIME

Figure 1 illustrates the relationship of swap-in delay with TSO response times as observed on a 3084Q processor, configured with 64 megabytes of main memory. The erratic nature of TSO response time is clearly observable, suggesting that for various times during the shift, users are subjected to erratic response times. Also, a clear correlation between consistently low response time and swap-in delay less than 25 milliseconds is observable. The erratic response time can be easily corrected by employing a more robust swap subsystem. It should be pointed out that any swap subsystem has its capacity (in terms of I/O load); as I/O loads fluctuate close to or even exceeding that maximum load even momentarily, one can expect that response times will degrade. Hence, it is essential to ensure that such subsystems are carefully configured to accommodate expected peak I/O loads and even some unexpected ones (i.e. reserve capacity).

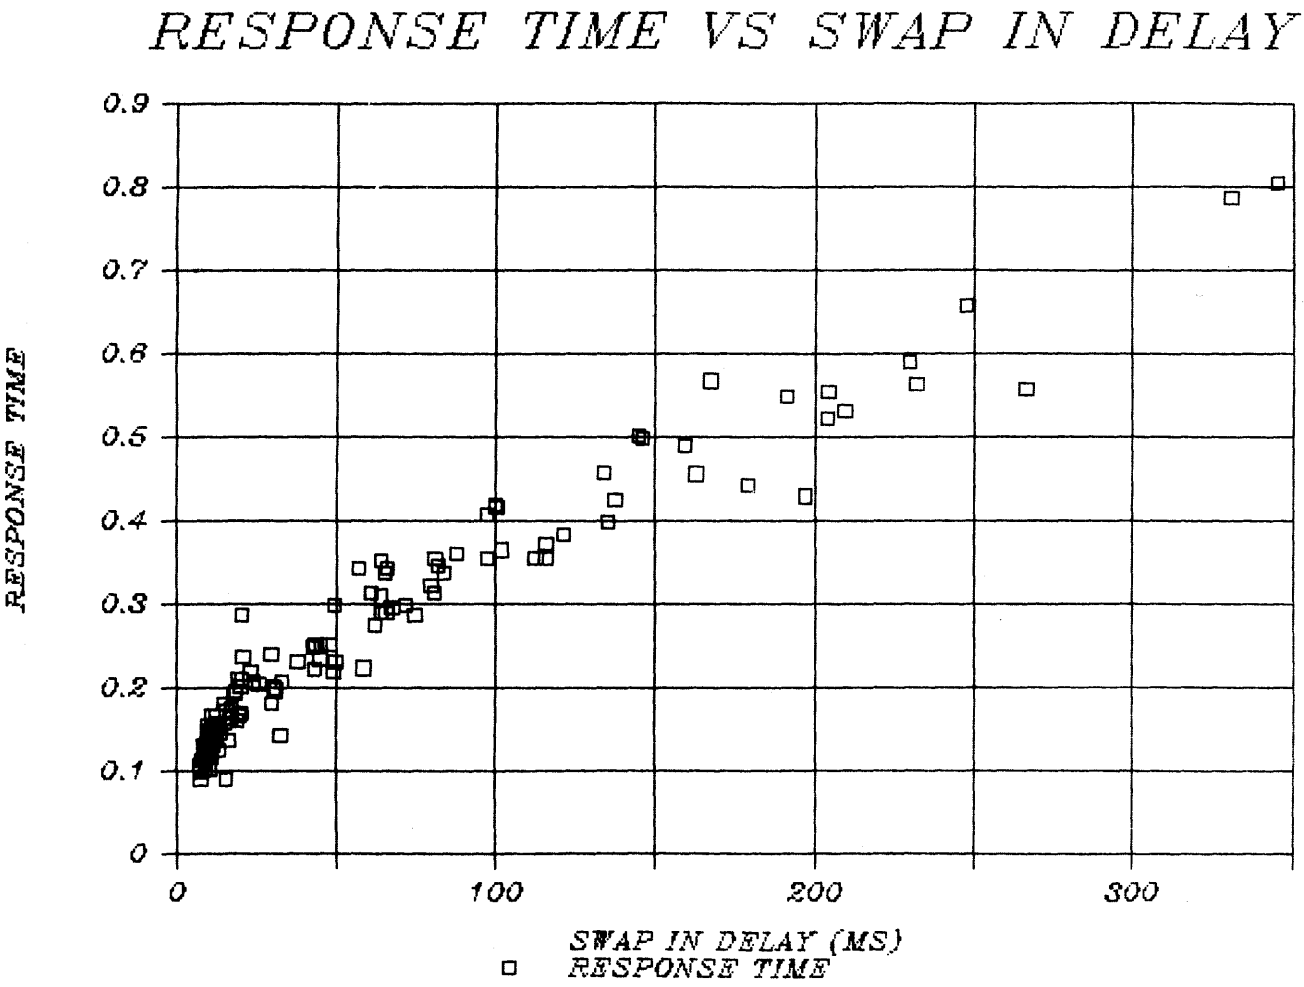

FIGURE 1 - RESPONSE TIME VS SWAP-IN DELAY (CUSTOMER DATA)

MEMORY TUNING ISSUES

LOGICAL SWAPPING

The effective use of logical swapping is a means of lowering the quantity of physical swapping while, at the same time, providing low and consistent response times. Logical swapping is a process whereby a TSO user is kept in main storage until he is again ready to execute. The logical swap process is dependent on the logical swap think time, which in turn is governed by the average system wide unreferenced interval count (UIC). Logical swapping may also be impacted by assigning certain values to the low and high thresholds of the available frame queue; the parameter, LSCTAFQ is discussed in [12].

While the overall benefits of logical swapping remain without question, the disadvantages of it are oftentimes somewhat elusive. The cost is simple: inactive users are guaranteed acceptable response times, sometimes at the expense of the active users.

UNREFERENCED INTERVAL COUNT (UIC)

If the amount of available real memory within the processor remains high, one can and should indulge in logical swapping; this should only be done in conjunction with low demand page rates. On systems with a high amount of logical swapping and high demand page rates, something more is needed; an examination of the unreferenced interval count (UIC), and the available frame queue (AFQ) is necessary

The UIC values for any given system is an indicator of memory busyness; it is typically a high value (max of 255) on systems that exhibit little or no contention for memory. A low system wide UIC (minimum 0) is a clear indicator of high memory contention. The use of logical swapping can be interpolated amongst the values for UIC and the available frame queue.

AVAILABLE FRAME QUEUE (AFQ)

The available frame queue AFQ is a reported statistic within RMF and is another indicator of memory contention. As a matter of fact, the depletion of the AFQ results in supervisor state activities which involve page stealing. It is desirable to minimize page stealing at all costs. In all the cases studied, the obvious relationship between a low or even depleted AFQ and high page-in rate for the system was observed.

STORAGE ISOLATION

Storage isolation is a facility available to the performance analyst that permits the protection of an application's working set and/or common area. The critical working set is determined and the low and high paging threshold values are set; the system now attempts to maintain the working set as defined within those thresholds. If however, memory contention sets in (low UIC, depleted AFQ etc.), the system will eventually steal pages from the protected applications.

The overall recommendation of storage isolation evidenced in both Pierce [4] and [13] is to suggest that storage isolation values (if necessary) "be selected with care and monitored closely".

In at least two of the cases studied, storage isolation was defined for "critical" applications since they shared memory with TSO and others; by reducing logical swapping in these environments in conjunction with the removal of storage isolation, more "free" memory was allowed to exist , overall system response times improved and further storage isolation became unnecessary.

MEMORY BUYBACK

Upon careful evaluation of certain large MVS systems (3081, 3084, and 3090), it was observed that a threshold amount of logical swapping was beneficial; the elimination of some (the majority) of it resulted in a better economic solution to response times and overall system throughput.

Decreasing logical swapping is achieved by lowering the system think time; this is accomplished by setting/resetting the upper and lower bounds of the LSCTMTE parameter of MVS. The effect of that (e.g. LSCTMTE=(5,10)) would suggest to MVS that users with a think time of 5 seconds or less should be logically swapped, and users logically swapped for more than 10 seconds are to be physically swapped; such a setting for think time may see logical swapping decrease from the high ninety percent range to the low twenty percent range. That resulted in a significant amount of real storage being freed, thus leading to a dramatic increase in the size of the available frame queue. The resulting increased physical swap rates can be handled easily by an appropriate number of disk actuators or a pre-determined amount of solid state disk.

The rationale for the above action is essentially predicated on two main reasons. In the first place, users that take a long time to think of their next action should not tie up a valuable resource such as memory; they should be removed in favour of the "fast thinkers". Secondly, main memory availability determines the quantity of logical swapping within the system; it is a fluctuating quantity, which influences the systemwide UIC values and the unused frame count. Hence, one must judiciously oversee the overall committment of main memory to logical swapping, since periodic overcommitment can and will result in storage contention (low UIC values), and even, page stealing when the unused frame queue becomes depleted.

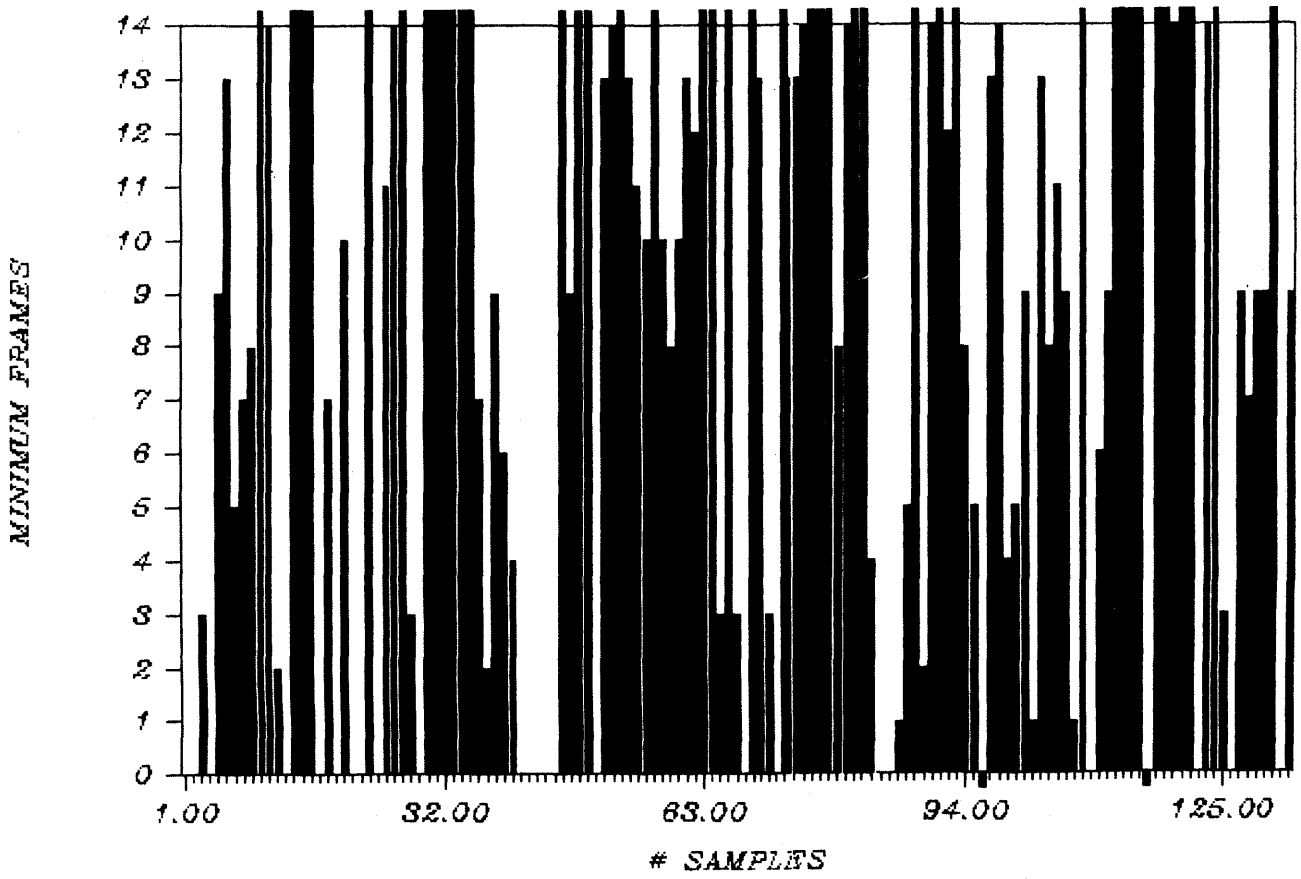

FIGURE 2 - MINIMUM FRAMES DURING PEAK SHIFTS (CUSTOMER DATA)

Figure 2 details the fluctuating values for the available frame queue on a 3084 processor with 64 megabytes of main memory, while the quantity of logical swaps was averaging about 85 percent. That situation was easily rectified by lowering the system think times, which resulted in a lowering of logical swapping, an overall reduction of the page-in rates, an increase in physical swapping, and an increase in the UIC values for unreferenced frames.

The amount of memory freed (buyback) is evidenced in Figure 3. In at least one instance, the "buyback" of existing real storage served to decrease the demand page rates significantly. Upon further analysis, it was also observed that other workloads benefited from the decrease of the demand page rates; a primary beneficiary was IMS. On other systems, one may expect the primary beneficiaries would be any shared address space. The benefit conferred upon IMS (a significant decrease of demand paging) is illustrated in Figure 4.

In achieving the aforementioned results, the available frame queue increased dramatically and system wide UIC values were lowered (although not to the point that would suggest increased memory contention).

EXPANDED STORAGE

The 3090 series processors provide the option of an additional amount of memory that can be used as a repository of page and swap pages; this is known as expanded storage. Transfers of pages from expanded to main and vice-versa occurs in units of 4K. The expanded storage is under the control of the real storage manager, and it is not user addressable. This level of storage is not as costly as main memory, but, to date, remains more expensive than any currently available external page/swap subsystem.

Expanded storage holds pages that were infrequently used in main memory, as well as logically swapped TSO users. This can be viewed as yet another option of tuning main memory since pages that are least recently used (LRU) are LRU'ed out to expanded storage by the real storage manager.

Various experiences with expanded storage suggest the following: reduction of paging and its associated I/O, hence better response time; little or no additional throughput. In fact there is mounting evidence to suggest that due to the synchroneity of the processor during page reference to expanded storage, the

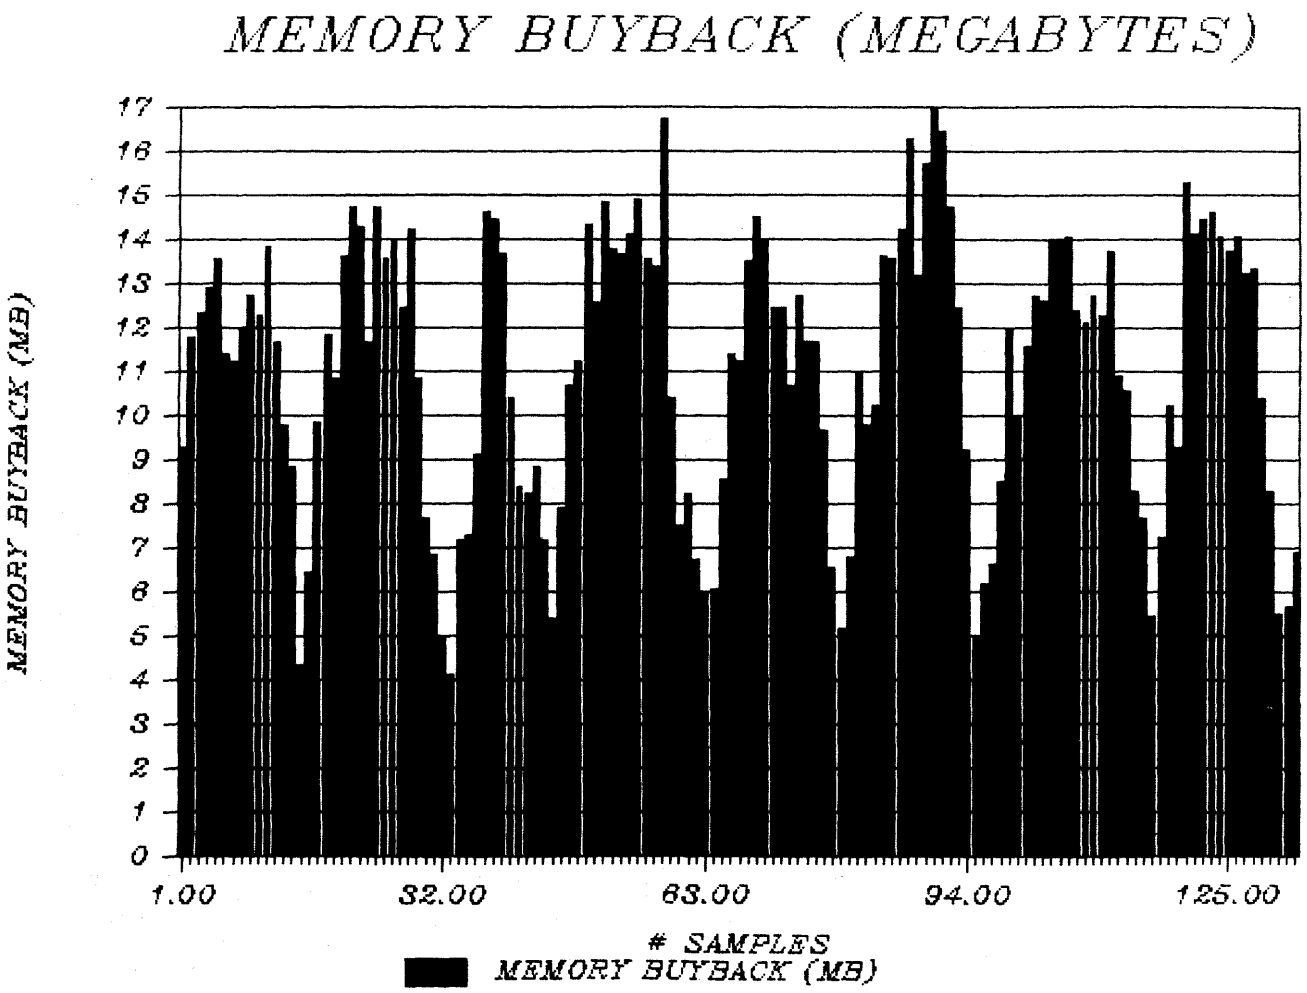

FIGURE 3 - MEMORY USED (LOGICAL SWAPPING ONLY) DURING PEAK SHIFTS (CUSTOMER DATA)

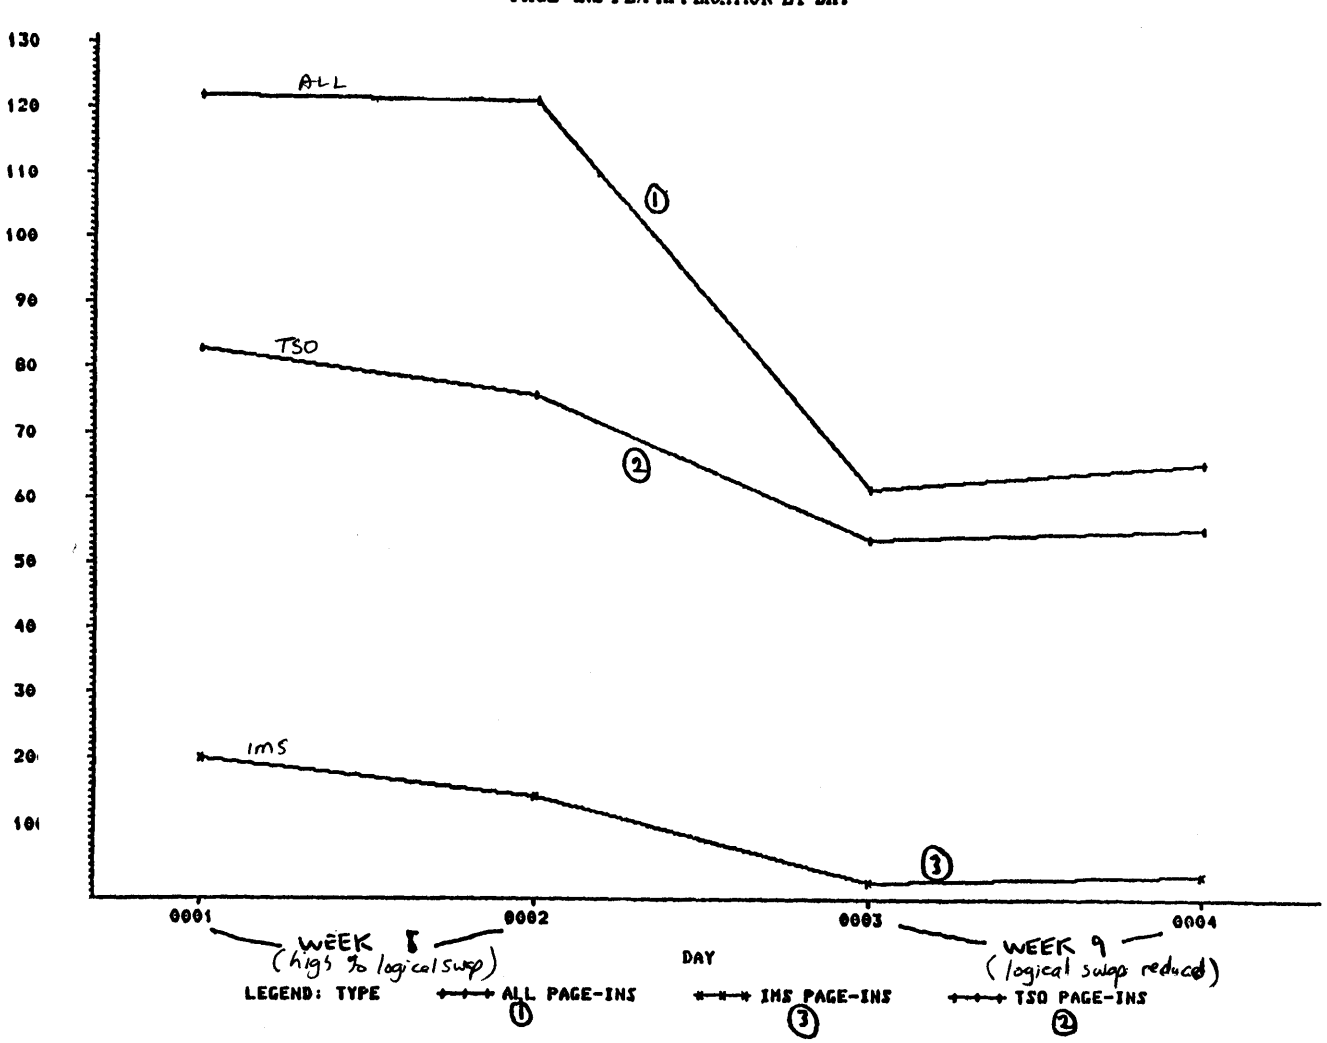

FIGURE 4 - AVERAGE DAILY PAGE-INS PER SECOND DURING PRIME SHIFT - BY APPLICATION (CUSTOMER DATA)

quantity of traffic to and from expanded storage imposes some very real constraints on processor throughput.

Other vendor's implementation of expanded storage involve the logical partitioning of the available real memory. The experiences thus far, suggest that this approach is not similarly constrained as the 3090.

SHARED vs UNSHARED ADDRESS SPACES

A shared address space such as IMS or CICS allows multiple users to execute within it. An unshared address space is one that facilitates only one user to execute within it; this is typified by TSO.

The fundamental difference between the shared address space and the unshared one, in terms of their respective memory requirements is the following: when a page fault is suffered by a shared address space, all users within it wait until it is resolved, even though it may have been caused by one distinctive reference on the behalf of one user. When a page fault is suffered by an unshared address space, only that user waits.

In terms of the reference strings so evolved, the shared address space will tend to exhibit a more diffuse locality of reference for its reference string W(T), since it is attempting to satisfy the requirements of many users during the reference interval t. The unshared address space reference string W(t), and working set size s(i) is such that

$$s1(i), s2(i), \ldots, sm(i)$$

accounts for the locality patterns for m unique users within the address space and thus, represents m mutually disjoint locality sets. Further, the m locality sets identified, may be unequal in cardinality (unlike TSO), and would each generate their own reference string. A more diffuse locality of reference across the working set s(i), will result in a higher probability that the frame that needs to be re-referenced will be stolen prior to that re-reference and hence, a page fault will be suffered. This provides the basis for different memory considerations for such address spaces.

The TSO user, on the other hand, enjoys great consistency across reference intervals (swap-ins), and thus contributes to a smaller locality of reference.

COST/PERFORMANCE ISSUES

Throughout, the issues of determining the judicious usage of memory has been discussed, and alternatives presented. The capacity planner may still agree that recommending memory so as to reduce paging and/or swapping is the safest and most proven thing to do. However, one should consider the useful remaining lifetime of the intended processor and the cost of acquiring more real storage versus the adoption of an optimal paging/swapping subsystem, and then proceed from a cost/performance viewpoint.

Table 1 details the relative cost of the various storage alternatives along with their response time characteristics (swap-in delay, standard deviation). It is readily apparent that real storage (highest cost) will undoubtedly render the best performance in terms of low and consistent response times. Expanded storage, which is relatively cheaper than real storage may work well (almost zero swap-in delay) until the page movement to and fro increases, at which time, throughput and response times may be negatively impacted. The solid state disk affords the user a small swap-in delay (10-25 milliseconds), coupled with a flat, consistent service time at a lower cost.

The consequences of zero swap-in delay is obvious; that of 10-25 milliseconds serves to increase the TSO response time by 0.01 to 0.025 seconds -- the effect upon the user is negligible.

	SWAP-IN DELAY	STANDARD DEVIATION	RELATIVE COST
REAL STORAGE	0	LOW	4
EXPANDED STOR	~0	LOW	3
SOLID STATE	10-25	CONSISTENT	2
ROTATING DISK	30-??	ACCEPTABLE ?	1

COST: 1 (LOWEST) - 4 (HIGHEST)

TABLE 1 - SWAP-IN DELAY AND RESPONSE TIMES FOR VARIOUS DEVICES

It should be realized that the cost, configurational flexibility, performance and portability of a high speed paging/swapping subsystem will allow any environment a considerably better level of cost/performance.

CONCLUSION

Current processors already offer a myriad of main memory sizes in addition to the minimum recommended (standard) amount for that particular machine; in addition to that, some others even offer expanded memory. The decisions for the capacity planner with respect to configuring an optimal amount of memory can be as simple as "all that can be configured" or "all that can be effectively utilized".

The "better safe than sorry" attitude of some capacity planners often leave little recourse for pursuing a detailed analysis of memory useage; that forms a stark contrast against those who relentlessly search for "optimal solutions" for their problems. There is no performance or capacity problem that can't be solved by "throwing" hardware (money) at it.

Shared address spaces have a somewhat different memory requirement from non-shared address spaces such as TSO. Optimizing memory is simply a matter of interpreting the indicators of contention within the context of the existing workload; all workloads are not created equal and hence, all machines need not be configured the same!!

ACKNOWLEDGEMENT

I would like to thank my wife, Saroj for her painstaking efforts in the typing of this manuscript; also, for her patience and understanding during her many lonely hours while I prepared it. Special thanks to Paul Hill, Andy Kendal, and Dave Irwin for their valuable input from time to time.

Estimating the Maximum Throughput of a CYBER 930 Disk Subsystem

Andrew Tron
John Sutherland

Control Data Canada Ltd.
1855 Minnesota Court, Mississauga, Ontario

ABSTRACT

A way of estimating the maximum throughput of a disk I/O subsystem is presented by way of a case study of a Control Data CYBER 930 Disk Subsystem. The method used is based upon queueing network theory. Results are presented and the feasibility of applying this method to other systems is discussed.

1. INTRODUCTION

Disk I/O subsystems play a critical role in computer system performance. Because of this, knowledge of the maximum throughput of a disk I/O system is quite important in designing computer systems. If service demands in a disk subsystem were fixed, it would be trivial to calculate maximum throughput. Unfortunately this is not the case as a significant portion of the service demand at a disk drive may represent the effect of channel contention. Channel contention is the time the disk drive waits for a control device to be free of requests from competing disk drives. The amount of contention varies with the system load: the busier the system, the greater the channel contention. Another key factor which is often not considered is the effect of software overhead in the I/O driver itself.

In this paper a method of estimating the maximum throughput of a particular disk I/O system based upon queueing network theory is presented. The system under study is a Control Data CYBER 930 Disk Subsystem. A brief description of the system and a discussion of the queueing model used are presented in Section 2. Section 3 details the method used to evaluate the model to get the maximum throughput. Results are discussed in Section 4. Generalizations of this method to other types of disk I/O systems are presented in Section 5.

2. A BRIEF DESCRIPTION OF THE CYBER 930

The CYBER 930 is a midrange computer system characterized by an extremely large virtual memory and massive I/O bandwidth. The maximum possible system I/O bandwidth is 80 megabytes per second with up to 20 megabytes per second being architecturally possible on any individual channel. The system architecture is the standard Control Data CPU/Peripheral Processor (PP) architecture with significant extensions in the I/O subsystem:

- Peripheral processors are discrete rather than "slot and barrel" (i.e. timeshared) resulting in much faster execution of PP code.
- Peripheral processor memory has been quadrupled.
- Direct memory access (DMA) capability has been added allowing data transfers directly between peripheral processors and central memory rather than requiring them to be buffered through PP memory. However the PP remains tied up for the duration of the data transfer.
- Support for the forthcoming ANSI standard Intelligent Peripheral Interface (IPI) channel with transfer rates up to 10 megabytes per second (as opposed to the 3 megabytes/second maximum for the C170 channels used on previous CYBER 180 models).
- Additional instructions designed to reduce PP overhead for I/O setup.

The net effect of these changes is a significant improvement in both I/O setup time and data transfer rates compared to previous Control Data CYBER models as well as the complete elimination of one processing stage (data transfer between PP memory and central memory).

2.1 A DESCRIPTION OF THE CYBER 930 DISK SUBSYSTEM

A CYBER 930 Disk Subsystem consists of three types of devices: peripheral processors (PPs), control modules and disk drives. The PPs are the interface between the disk subsystem and central memory. Up to eight control modules may be attached to a PP via an Intelligent Peripheral Interface (IPI) channel. The control modules provide an interface between the disk drives and the peripheral processor, and provide control signals for the disk drives. The disk drives are Control Data FSD-2's which employ rotational position sensing (RPS) to optimize channel usage.

The transfer rate of the disk - control module channel differs from that of the IPI channel which means that the control module must be buffered for speed matching. A single-path architecture is used: each disk is connected to only one control module, and each control module is connected to only one peripheral processor. A block diagram of the disk subsystem is shown in figure 1.

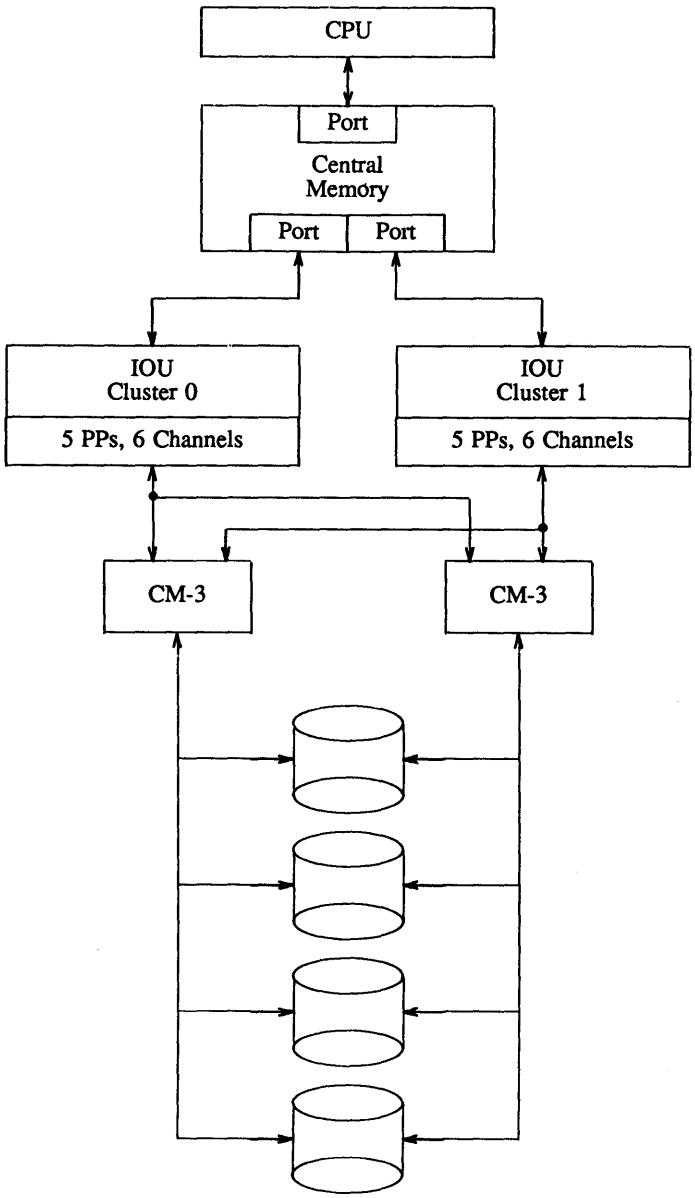

Figure 1 - Block Diagram of CYBER 930 System

Note that physically each control module is connected to two channels and each disk to two control modules. However this is a static (under software control) rather than dynamic dual access intended to provide redundancy for fault tolerance purposes. Logically the O/S software only uses one channel to each control module and drives each disk from a single control module.

Each PP is a specialized I/O processor which can transfer data between its own memory and a device on a data channel or can initiate and control a data transfer on a DMA path between central memory and the device. PPs are packaged in an I/O cluster having five PPs and six channels. A CYBER 930 can have one or two I/O clusters giving a maximum of ten PPs and twelve channels.

The control module (CM-3) is a microprocessor based disk controller with two IPI channel access paths which is capable of controlling up to eight disks. In a CYBER 930 configuration, a maximum of four disks are supported on a CM-3. The CM-3 is a buffered device having a 96K data buffer which allows it to speed match between the 10 megabytes per second transfer rate on the mainframe side and the disk transfer rate of 1.82 megabytes per second for a FSD-2 drive. The CM-3 has a software latency of about 3 milliseconds for decoding commands.

The FSD-2 disk (also known as the CDC 9836) is a nine inch sealed module drive with a formatted capacity of 414 megabytes. The disk uses a fixed block architecture with a sector size of 2048 bytes. Its nominal data transfer rate is 1.88 megabytes/second which is adjusted to 1.82 megabytes/second to allow for intersector gaps. The theoretical average seek time of the FSD-2 is 20 milliseconds.

2.2 THE MODEL OF THE DISK SUBSYSTEM

Since the control module is buffered, an I/O request can be divided into two operations: transferring data between the disk and the control module, and transferring data between the control module and central memory. This involves first queueing for the disk and then queueing for the disk drive - control module channel. In the model, this operation is represented by including each disk drive as a service centre. The wait involved in queueing for the disk drive - control module channel is incorporated into the service demand of each disk drive as channel contention. The second operation involves the control modules and the central subsystem queueing for the peripheral processor, which can be represented in the model by including the peripheral processor as a normal queueing centre. Because the control module operates in parallel with the disk and the peripheral processor, there is no need for it to be directly represented in the model.

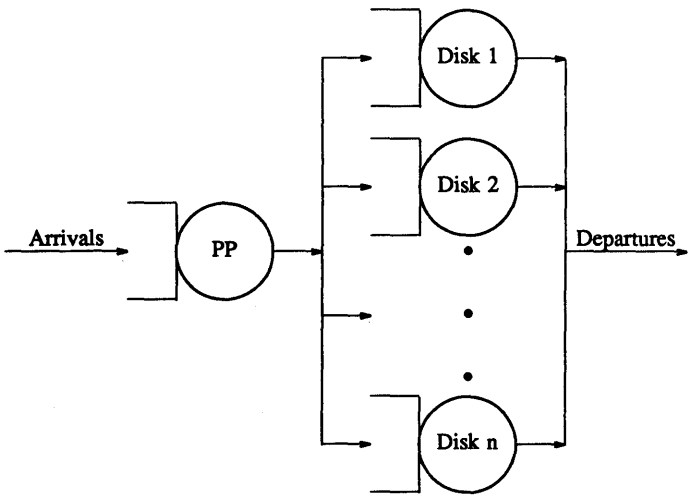

Figure 2 -- Diagram of Queueing Model

The customer population is modelled as a single open class with each transaction representing a single I/O request. When all devices are homogeneous, maximum throughput is achieved by balancing the load across all devices. Thus it is assumed that the disks have identical performance characteristics, the visit counts for all the disks are identical, and the same number of disks are attached to each control module. These assumptions simplify calculations. Furthermore, the system is modelled with only one peripheral processor. Systems with two or more peripheral processors can be subdivided and evaluated as separate systems.

3. METHOD OF SOLUTION

Maximum throughput occurs when the device with the largest service demand is saturated. Let X_{max} be the maximum throughput and let D_{max} be the largest service demand in the system. Then by the utilization law (Utilization = Throughput × Service Demand):

$$D_{max} \times X_{max} = 1$$

To find the maximum throughput, set D_{max} to each of the service demands in the model and then solve the above equation for X_{max}. The lowest value of X_{max} obtained is the maximum throughput of the system. Since the disks all have equal service demands, one need only find the service demand at the PP and at one of the disks.

3.1 MAXIMUM THROUGHPUT AT THE PERIPHERAL PROCESSOR

At the PP, the service demand consists of the time taken to transfer data between the control module and the peripheral processor plus PP overhead. The transfer rate of the IPI channel between the PP and control module is 10 megabytes/second. A rough approximation of the overhead can be obtained by assuming 600 μs per request plus 100 μs for every 2048 bytes transferred, from [2]. A more accurate, but more complex, expression for the overhead is found in Appendix A.

Let D_{pp} be the service demand at the peripheral processor and let B be the block transfer size in bytes. Then:

$$D_{pp} = \frac{B}{1.0\times10^{7}} + \frac{B\times0.0001}{2048} + 0.0006$$
$$= B \times 1.488 \times10^{-7} + 0.0006$$

Assuming that this is the bottleneck in the system, the maximum throughput then is:

$$X_{max}(pp) = \frac{1}{D_{pp}}$$
$$= \frac{1}{B \times 1.488 \times10^{-7} + 0.0006}$$

3.2 MAXIMUM THROUGHPUT AT THE DISKS

The service demand at the disks drives consists of four components: seek, latency, data transfer and channel contention. An average seek time of 14 ms is used which includes overhead of about 3 ms at the control module. This estimate of the average seek time is based upon empirical data from various benchmark runs and is less than the theoretical average of 20 ms with files evenly distributed over the disk. The reasons for this difference between observed and theoretical seek times have been discussed in the literature ([3] and [4]). The authors are aware of only one case where the theoretical average seek time has been observed on a production system [5]. The average latency period is 8.33 ms which is half the average rotational period. The average data transfer time is calculated by dividing the block size by the data transfer rate of 1.82 megabytes/second. The channel contention component cannot be parameterized as easily because it is dependent upon the system load. However channel contention time can be expressed as a closed-form function of the system throughput.

Let x be the system throughput,
s be the average seek time,
l be the average latency period,
t be the average data transfer time,
a be the average channel contention,
c be the number of controllers,
d be the number of disks per controller.

Then:

a = *rotational period* × *average number of reconnect attempts*
$= 2 \times l \times$ *average number of reconnect attempts*

In an RPS system in which the disk "sees" one level of control devices, the average number of reconnect attempts is given by [1] as:

$$\frac{U_{CM} - U_{CM}(disk)}{1 - U_{CM}}$$

where U_{CM} is the utilization of the control module, and $U_{CM}(disk)$ is the utilization of the control module due to transfers by a particular disk. U_{CM} equals xt/c, and $U_{CM}(disk)$ equals xt/cd, so that:

$$\frac{xt(d-1)}{d(c-xt)}$$

is the average number of reconnect attempts. Therefore:

$$a = \frac{2lxt(d-1)}{d(c-xt)}$$

The average service demand at the disk is then given by:

D_{disk} = *Visit Count* × $(s+l+t+a)$

$$= \frac{(s+l+t+a)}{(c \times d)}$$

since it was assumed that the system load is balanced equally across all $c \times d$ disks.

Assuming that the bottleneck occurs at the disk, the maximum throughput is found by solving the equation

$$D_{disk} \times X = 1$$

for X. This equation can be expressed as a quadratic:

$$X^2 [dt(s+l+t) - 2lt(d-1)] + X [-cd(s+l+t) - cd^2t] + c^2d^2 = 0$$

and solved for X by the quadratic formula, using the smallest positive solution as the maximum throughput.

4. NUMERICAL RESULTS

Ten system configurations were considered: 1, 2, 4, 6, and 8 control modules per PP, with 2 or 4 disks per control module. Each configuration contained one PP. Configurations are designated by the total number of control modules and disks: a system with 4 control modules each having 4 disks is designated as a 4 x 16 system. Sixteen transfer block sizes were considered for each system configuration: from 4 to 64 kilobytes with an increment of 4 kilobytes.

Two results are shown graphically for each system configuration: maximum throughput in requests per second and maximum throughput in megabytes per second. The latter is calculated by multiplying the former by the transfer block size and is a more useful statistic since it gives an indication of the maximum rate of information transfer. These results are graphed in figures 3 to 6.

As expected, the maximum throughput in terms of requests per second decreased with increasing block size and the maximum throughput in terms of bytes per second increased with increasing block size. The maximum throughput of the IPI channel between the PP and the control module never exceeded 6 megabytes/second. Since it is rated at 10 megabytes/second, the maximum utilization of the channel is approximately 60%. This confirms a rule of thumb which states that the system performance drastically deteriorates when the utilization of the channel approaches 60%. The graphs also demonstrate that the channel supports up to four control modules quite efficiently. However there is only marginal benefit in adding additional control modules beyond four, especially with four disks per control module.

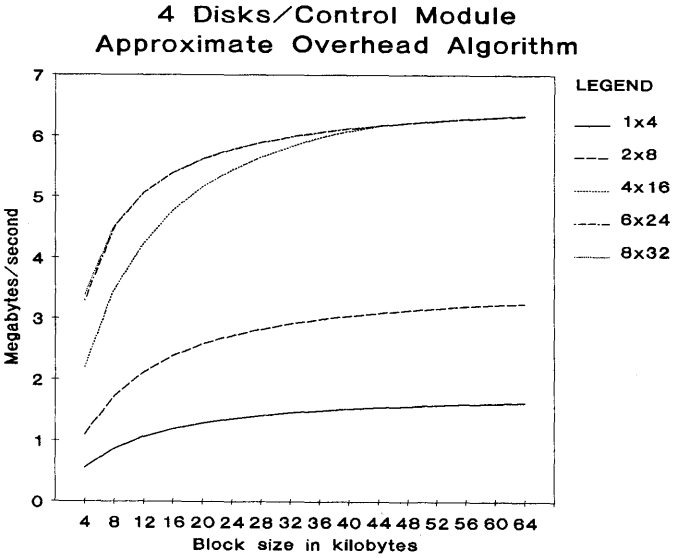

Figure 6

5. GENERALIZATION TO OTHER SYSTEMS

This method of estimating the maximum throughput of a disk subsystem can be generalized to other systems provided that the service demands in the resultant queueing models of those system are either constant or closed-form functions of system throughput. The formula for the disk service demand used in this study was taken from [1]. This book provides closed-form formulae for the following cases: single-path non-RPS architecture with one level of control devices and single-path RPS architecture with one or more levels of control devices. Once these formulae are known, the maximum throughput can be found by following the method outlined in Section 3.

This study also incorporates an analytical expression for the PP based I/O driver overhead. Often this data is not available. We were able to obtain this information directly from the developer of the I/O driver who had done detailed path timing analysis [2]. For other architectures, I/O driver overhead may occur in the CPU or in other elements of the I/O subsystem. As always in performance evaluation, the difficulty lies in understanding where the significant contributions to I/O processing time actually occur.

In general, this method does not work for systems that employ multipathing. For these systems, the proportion of the requests of a disk that use a given path is usually unknown. An iterative algorithm must be used to find the proportioning of the requests of a disk among possible channels and the service demand of the disk cannot be expressed as a closed-form function of the system throughput. However, there are some multipathed systems where the proportioning of the requests of a disk across channels is known a priori. An example is a system where all possible connections between devices on one level and devices on the next level are made. In this situation the requests of a disk are distributed uniformly among all possible channels, allowing the disk service demands to be expressed as a closed-form function of system throughput.

The formula used to calculate the disk service demand assumes a single level of control devices. There are actually two levels of control devices in the system but because the control module is buffered, the disk only "sees" one level of control devices. In general, the formula used to calculate disk service demand should be based on the number of levels of control devices that a disk "sees". Any further levels that are buffered away should be treated as separate service centers.

In this study, the I/O activity was assumed to be balanced across all of the disks. Had this assumption not been made, it would have still been possible to estimate the maximum throughput. The computations are then more difficult as an expression for the service demand at every disk must then be found and the disk throughputs summed.

A thorough treatment of RPS reconnect delays is found in [6]. Another approach to modelling multilevel I/O subsystems is the method of surrogate delays detailed in [7].

6. LIMITATIONS

This study only addresses the saturation case where there are always I/O requests pending for each device. As soon as one request completes, another is ready to be processed. There is also no consideration given to the CPU time required to generate and post an I/O request. For example, if the CPU time for each I/O request were 2 milliseconds which is not unreasonable for this class of system, the maximum I/O rate would be limited to 500 requests/second because of CPU saturation.

Another assumption made is that the distribution of I/O requests is uniform across all devices and control modules. Although this is almost never achieved in practice, it is a reasonable assumption because we are trying to determine the maximum possible throughput for the disk subsystem which occurs when the load is evenly distributed. As was previously noted, the solution technique used here is still usable without a uniform distribution albeit with additional computational complexity. Other factors which affect these results are the mean seek time and the distribution of seek time. In this study, we have assumed an average seek time of 11 milliseconds based on measured results from benchmarks. However this is highly dependent on the workload type and on the amount of tuning done on file placement.

Further studies are planned to determine the effects of these factors.

7. CONCLUSIONS

A method based upon queueing network theory of estimating the maximum throughput of the CYBER 930 Disk Subsystem has been devised. A queueing model of the system was constructed and parameterized. The computations involved with this model are easy and can be done by hand if necessary.

The results were graphed for different disk configurations and different transfer block sizes. They predict that no significant benefit is to be gained by having more than four control modules per peripheral processor. In fact the graphs for the exact overhead algorithm show that performance actually degrades if there are more than four control modules on a channel.

As well, they predict that the maximum throughput in terms of megabytes per second increases with increasing block size and that the maximum utilization of the control module - peripheral processor channel is approximately 60%, both of which are in agreement with empirical data. However this method has not been otherwise validated.

From this analysis, the expected peak disk transfer rate on any individual channel is about 5.5 megabytes per second for FSD-2 class disks. A typical large CYBER 930 configuration has four disk channels. This means that an aggregate disk transfer rate of 22 megabytes per second could be attained. In fact as was discussed in Section 6, we would expect the CPU to become saturated well before this throughput level could be reached.

This method can easily be adapted to work for many other disk systems.

APPENDIX A - A MORE ACCURATE EXPRESSION FOR PP OVERHEAD

The algorithm used in this paper to calculate the peripheral processor overhead is fairly accurate for small block sizes but underestimates the overhead for larger block sizes. The reason for this is that the peripheral processor deselects from a control module after three sectors of 2048 bytes each have been transferred in order to multiplex to other units. If more than three sectors need to be transferred, the control module needs to be reselected, causing an increase in overhead. A more accurate algorithm to calculate the PP overhead is given by [2] and shall now be presented.

In this algorithm the PP overhead can be divided into four components: I/O setup, 6 kilobyte transfers, remainder transfers, and response to the CPU.

Let B be the block size in kilobytes,
P be the page size in kilobytes,
c be the number of controllers,
d be the number of disks per controller.

The initialization time is the time taken for initialization of the request.

$$\textit{Initialization time} = \frac{55+10\times cd}{2} + 230 + 13\times\left\lceil\frac{B}{P}-1\right\rceil \mu s$$

$$= 257.5 + 5cd + 13\times\left\lceil\frac{B}{P}-1\right\rceil \mu s$$

The 6 kilobyte setup time is the PP overhead associated with a transfer of a series of data bursts of 6 kilobytes each.

$$\textit{6KB setup time} = \left\lfloor\frac{B}{6}\right\rfloor\left(\frac{55}{2} + 10c + 75 + (3\times 85) + 25\right) \mu s$$

$$= \left\lfloor\frac{B}{6}\right\rfloor (382.5 + 10c)\ \mu s$$

The remainder setup time is the PP overhead associated with the transfer of the remainder of the block after no more 6 kilobyte burst transfers are possible.

$$\textit{Remainder setup time} = \frac{55}{2} + 10c + 75 + 85\times\left\lceil\frac{B}{2}\ mod\ 3\right\rceil + 25\ \mu s$$

$$= 127.5 + 10c + 85\times\left\lceil\frac{B}{2}\ mod\ 3\right\rceil \mu s$$

The response to the CPU is the time taken by the PP to tell the CPU that a transfer has been completed.

$$\textit{CPU response} = 177.5 + 10c\ \mu s$$

The total PP overhead is then found by summing the four components.

$$\textit{PP overhead} = 562.5 + 20c + 5cd + 13\times\left\lceil\frac{B}{P}-1\right\rceil + 85\times\left\lceil\frac{B}{2} mod\ 3\right\rceil +$$
$$\left\lfloor\frac{B}{6}\right\rfloor\times(382.5 + 10c)\ \mu s$$

Note that this expression does not include the data transfer time on the control module to central memory IPI channel path. The total PP service demand is the sum of the PP overhead and this data transfer time.

A more accurate estimate of the maximum throughput of the peripheral processor can be found by using this estimate of the PP overhead in the formula for the maximum PP throughput in section 3.1. This has been done and the results from these new calculations are shown in figures 7 through 10.

PERFORMANCE ARCHITECTURE COMPARISON OF VECTOR PROCESSORS ON LARGE SCIENTIFIC AND COMMERCIAL MACHINES

Dr. David S. Lindsay
National Advanced Systems

ABSTRACT

Using a benchmark described in a companion paper, this paper compares a Cray-XMP (an "engineering/scientific" machine) with an IBM 3090-VF and an NAS AS/XL, the latter two being "commercial" machines with vector processors.

The benchmark technique reveals such details as (1) the vector vs. scalar speed of each machine for various operations and vector lengths (and, therefore, what minimum vector length is required for the vector processor to surpass scalar performance); (2) the ability of vector processors to "chain"; and (3) the pipelining capability of scalar machines, as revealed by performance tests of "loop unrolling".

1. INTRODUCTION

A companion paper (Ref. 1) has described the design of a benchmark for vector architecture and performance comparison. That paper noted that performance is an even more important consideration for a vector processor than for a "normal" processor, since the sole motivation for vector processing is improved performance. With the advent of vector processors on general-purpose machines such as the IBM 3090, it is becoming imperative that CPE professionals adequately understand the performance of vector processors.

Briefly reviewing the benchmark approach described in Reference 1, the following characteristics are of central importance to vector performance:

1. Vector speed vs. vector length;

2. Vector vs. scalar performance;

3. Sensitivity to data caching;

4. Determining the processor's ability to "chain" (vector chaining is analogous to pipelining in a scalar machine--the ability to execute more than one vector operation simultaneously. See Ref. 1).

This list is not exhaustive, but it represents an essential first step in understanding vector performance. Naturally, these metrics may depend on what particular vector operation is being considered. Thus, it is important to check several operations, including the ones that will actually be used in practice. The rest of this paper presents such data for several important vector operations on a Cray-XMP, an IBM 3090-VF, and an NAS AS/XL.

In order to compare vector and scalar performance, this paper also reports results from the same benchmark in scalar mode. As pointed out in Reference 1, "loop unrolling" (described more fully in the next section) can be an important technique for improving scalar performance. Therefore, results from tests with unrolled loops are also presented in this paper.

This paper is organized as follows: Sections 2 through 9 present measurement data from several different vectorizable operations, one operation per section; Section 10 presents some general conclusions about the three machines measured; Sections 11 and 12 present recommendations for users and manufacturers of vector processors, based on the measurement data; and Section 13 presents concluding remarks.

The measurement data show that many of the performance features of vector processing are common to all the tests. Therefore, this paper discusses these common features at length in Section 2 (which also describes the first test); successive sections describe only differences from the properties of Section 2, and are thus considerably shorter.

2. VECTOR ASSIGNMENT

This test measures the CPU speed of the following FORTRAN construct (or its vectorized equivalent):

```
      Do 2 i = 1, N
2     X(i) = Y(i)
```

Surprisingly, although this is a very simple test, its results yield most of the relevant information about vector and scalar performance. Measurement data are now presented:

2.1 CRAY-XMP RESULTS

Figure 1 presents the results of this test on a new Cray-XMP/416. (The significance of "new" is that the machine had a cycle time of 8.5 nanoseconds; most previous Cray-XMP's had 9.5 nanosecond cycle times). The "416" part of the designation specifies four CPU's and 16 mega-words of memory. Since this benchmark requires less than one mega-word of memory.and runs in a single CPU, the results would presumably be the same for other configurations of Cray-XMP CPU, so long as the cycle time remained the same (8.5 nanoseconds).

All figures in this paper have the same axes and scales as Figure 1, except where specifically noted in the text; the horizontal axis represents the logarithm (base 10) of the vector length, so that the origin (0) represents a vector length of 1, "2" represents a vector length of 100, etc. The software that created the graphs extended the horizontal axis to 6 (i.e., vector length 1,000,000), although vector lengths actually ranged up to a maximum of 200,000 in these tests.

For uniformity, the vertical axes extend to 110 million operations per second (MOPS), where for the purposes of the graphs in this paper, an "operation" is one unit of whatever the test measures, no matter how complicated. In Figure 1, an "operation" is a complete assignment--that is, the load and store are not counted separately.

Turning now to the data displayed in Figure 1, the scalar performance figures only extend to a vector length of 500 (rather than 200,000 as do the vector results) because of the expense of running on a Cray coupled with the expectation of seeing no new features in the data beyond length 500 for scalar loops.

Vector code was generated by a vectorizing compiler (CFT Version 1.14E), and shows many interesting features. Although the test was simple (merely copying a vector from storage to storage), the qualitative features of this test are similar to the other tests on the Cray-XMP, as will be seen below. The main features of interest from Figure 1 are:

1. The Cray-XMP's maximum performance on long vectors was roughly 85 MOPS, although the 8.5 nanosecond cycle time of that machine should have permitted 118 MOPS. Some of this discrepancy might have been due to running in a busy environment (for example, the performance dip between vector lengths 2,000 and 20,000 was probably due to timing noise or higher than average interference from other jobs).

But an additional source of overhead was the limit on the vector registers of the Cray-XMP: only 64 elements. Therefore the Cray hardware cannot process a vector longer than 64; longer vectors are split into 64-element pieces by the software, and processed in a loop (referred to as a "sectioning loop"). There is evidently enough loop overhead, either in the hardware or the software, that the theoretical maximum speed of 118 MOPS was not achieved in this test (or any other test in this set of benchmarks),

2. Although performance did not come close to the theoretical maximum of 118 MOPS, it certainly exceeded half that value, indicating that the machine was able to process more than one operation (including both a load and a store) in two machine cycles. This performance figure demonstrates that the Cray-XMP was able to "chain" its vector instructions (see Ref. 1, Fig. 3)--the processor could overlap a vector load and a vector store.

3. Figure 1 also shows that very long vectors (length 1,000 or more) were required to reach the processor's maximum speed; a vector length between 50 and 100 was required to achieve half of that performance.

4. Interestingly, vector performance exceeded (or at least equaled) scalar performance for <u>all</u> vector lengths; and scalar performance rose to about 4 MOPS for a vector length of 10 or greater, and was close to that value even for a vector length of five. Therefore scalar performance seems to approach a maximum for small loop counts (5 or 10), whereas vector performance requires vastly longer arrays before its full promise can be reached (in fact, a strict interpretation of "full performance", namely one operation per machine cycle, was <u>never</u> reached for this or any other test).

2.2 SCALAR LOOP UNROLLING

The scalar data reported in Figure 1 appear to be too pessimistic--scalar performance of two or even three times that shown has been reported from other Cray performance tests (Ref. 2). This discrepancy suggested the use of "loop unrolling". As applied to the assignment test, loop unrolling would restructure the FORTRAN source to be:

```
      Do 1 i = 1, N, 2
      X(i) = Y(i)
1     X(i+l) = Y(i+l)
```

Such a construct places two assignment statements (referencing adjacent vector elements) in each pass through the loop, and therefore executes the loop half as many times. (Some additional logic is required to process the general case where N, the vector length, may be odd.) Performance improvement in this unrolled loop arises from two related effects:

1. There is half as much loop overhead;

2. There is twice as much "useful work" per branch instruction, potentially making pipelined machines operate much more efficiently.

It may seem that loop unrolling is clumsy, seldom used in real programs, and therefore only of academic interest; but, in fact, there are several reasons for believing that unrolled loop performance is more valid than that of the simple, straightforward scalar loop used in this assignment test:

1. The MFLOPS rate ("millions of floating point operations per second", not necessarily the same as MOPS in this paper) usually seen on the Cray-XMP in scalar processing is much greater than four (Ref. 2), suggesting that the simple assignment test is not an accurate gauge of real performance on real work;

2. "Real" programs have much more complex loops than the one used here--they have many instructions per loop, thereby drastically reducing the percentage effect of loop overhead, while simultaneously increasing the efficiency of heavily pipelined machines (and those high-performance machines are exactly the ones most likely to feature vector processors);

3. Some advanced compilers, such as the latest Cray compiler (not used in these tests), are reputedly able to generate unrolled code for the short scalar loops that could benefit from such a technique.

For all those reasons, the benchmark now includes (in addition to the standard "rolled" loops) unrolled scalar loops for all tests. There are three sets of unrolled tests, with 2, 5, and 10 iterations per loop. Figure 2 presents results from these unrolled tests, in addition to those shown in Figure 1. Again, scalar results from the Cray were only run for vectors up to length 500, due to the difficulty of arranging for Cray time coupled with the expectation of seeing no performance change for scalars beyond length 500.

Figure 2 also presents data from an IBM 3090-VF and an NAS XL (discussed below). Because of limitations in the software used to prepare the graphs, the legend for the curves is rather brief. The legends mean:

- Sca--Scalar;

- 2--Unrolled scalar loop with 2 iterations per loop;

- 5--Unrolled scalar loop with 5 iterations per loop;

- 10--Unrolled scalar loop with 10 iterations per loop;

- Vct--Vector code (generated by compiler or the Cray, and by hand for the IBM 3090 and the NAS XL);

- VAST--Vector code generated by the VAST pre-processor (NAS XL results only).

Figure 2 shows that a dramatic speed improvement was obtained on the Cray by loop unrolling: performance for longer loops climbed from 4 to 8, 15, and 19 million assignments per second when the loops were unrolled by 2, 5, and 10 iterations. Perhaps performance would improve further with more loop unrolling.

Note an important feature of the Cray unrolled scalar loops: they required long "vectors" for high performance. For example, with 10 iterations per loop, 50% of maximum performance was not reached until the "vector length" reached 20. In this sense, unrolled scalar loops on the Cray behave like vector operations.

Loop unrolling presents performance in a new light: while it makes scalar performance look better, it thereby worsens the machine's relative vector performance. If the Cray's scalar speed is believed to be about 4 MOPS (as it appears to be in this test without loop unrolling), the vector processor improved performance 21 times (to 85 MOPS); but if improved scalar coding techniques (such as loop unrolling) can boost scalar speed to 19 MOPS, then vector speed-up becomes only a factor of 4.5, considerably less stunning (but nonetheless impressive).

But regardless of the vector speed-up factor, the fact remains that the Cray's vector processor was always faster than its scalar processor on assignments of any vector length. So there was never a penalty associated with using the vector processor for assignments.

2.3 IBM 3090-VF RESULTS

Figure 2 also presents the results of the assignment test on an IBM 3090-200/VF. This machine was a dual processor, but since the benchmark only runs in one CPU, it is really a test of only a single CPU and its vector processor. The dual-processor nature of this machine should not affect the results in this paper.

Scalar code was generated by the IBM VS-FORTRAN 1.4.1 compiler; vector code was hand-assembled (the version of VS-FORTRAN that we had at the time the tests were run generated incorrect vector code in some cases).

There are several interesting features of the IBM 3090 results shown in Figure 2:

1. The maximum vector processing rate was about 20 MOPS, about the same as the Cray's unrolled scalar loop performance. But the IBM 3090's cycle time was 18.5 nanoseconds, so one operation per cycle would have yielded a processing rate of 54 MOPS. Thus, the IBM 3090 was not able to process the vector assignment in one cycle per element; it only reached about one REAL*8 assignment in 2.5 cycles.

The vectorized machine code consisted of a 128-element vector load followed by a similar vector store in a sectioning loop (the IBM 3090 that we measured had 128-element vector registers). Since the resulting performance was somewhat less than one assignment in two cycles, the IBM 3090 was not capable of vector chaining. This conclusion is also supported by the rest of the benchmark tests. The lack of vector chaining on a machine with vector registers is a particularly serious shortcoming, since extra machine cycles are therefore required to load and store data.

2. Unrolling the scalar loop made little difference for the IBM 3090; perhaps that machine is not sufficiently pipelined to take advantage of several instructions in a loop.

3. Unlike the Cray's scalar processor, the IBM 3090's scalar processor appeared to reach 50% of its maximum performance at a "vector length" of about two. There is evidently far less loop overhead (either hardware or software) on an IBM 3090 than on a Cray.

4. A significant difference between the results from the IBM 3090 and the Cray was the reduction in IBM 3090 performance for vector lengths above 2,000. This effect is probably due to exhausting the IBM 3090's cache--when the operands do not fit in cache, the vector processor must access main memory, resulting in lower performance. (The Cray does not have cache, so no such effect is visible in the Cray data.)

5. As was the case for the Cray, the IBM 3090 required long vectors to reach its maximum performance: performance did not achieve 50% of its maximum value until the vector length was about 30, and was still rising at a vector length of 200.

6. The IBM 3090's vector processor was slower than its scalar mode when the vector length was less than 20 or 30 (the exact length depends on the level of scalar loop unrolling that is considered). This vector performance is considerably less impressive than the Cray's, which appeared to be faster (or at least no slower) in vector mode for any vector length.

7. A related feature of Figure 2 was that the maximum vector speed-up was much smaller for the IBM 3090 than for the Cray: a factor of slightly less than two.

8. The IBM 3090's scalar performance was higher than the Cray's unless loop unrolling of five or ten iterations was used.

There are two possible architectural reasons for the Cray's relativeiy poor scaiar performance (compared with the IBM 3090's) on rolled loops:

1. The Cray has 15 cycle memory and no cache. Thus loads from memory are forced to consume 15 machine cycles in all cases; the only hope for increased speed is the possibility of executing some other useful work while a load is in progress.

2. The Cray does not have "multiple instruction stream" capability, the ability to begin execution of both possible instruction streams before the outcome of a branch is known. The IBM 3090 and the NAS XL have such a capability, reducing the impact of a branch instruction on their pipeline performance.

Both of those architectural differences could make the Cray's scalar processor highly dependent on loop length.

2.4 NAS XL RESULTS

Figure 2 also presents benchmark results from an NAS AS/XL VIOO, a quadruple processor. As with the Cray and IBM 3090 tests, the benchmarks ran on one CPU; presumably the others would show identical results. This NAS XL CPU included a vector processor and had an 18 nanosecond clock, very close to the IBM 3090's 18.5 nanosecond clock. Thus any significant differences between the IBM 3090 and NAS XL performance reflect a difference in the number of machine cycles required to perform an operation--an architectural difference.

Unlike the Cray and the IBM 3090 vector processors, the NAS XL is a "memory-to-memory" machine: it has no vector registers. Thus one would expect that the NAS XL would not exhibit the "sectioning" overhead that was evident in both the Cray and IBM 3090 data.

The NAS XL scalar results in this paper were generated by runs from the same object code as the IBM 3090 runs (the NAS and IBM machines used in this study were in the same data center, and are instruction-compatible for all scalar instructions).

The figures also present results from both hand-assembled vector code and FORTRAN code generated by the pre-processor VAST (a product available for the NAS XL that processes FORTRAN code and inserts library calls to implement vectorization). The machine-generated code obviously had more overhead than the hand-assembled code, probably due to subroutine linkage. Both sets of code produced the same maximum performance. The graphs suggest the following observations:

1. The maximum speed of the NAS XL vector processor (for either method of code generation) was about 53 MOPS, which was very close to its theoretical limit (one operation per 18 nanosecond machine cycle, or 56 MOPS). This speed demonstrates that the NAS XL was capable of chaining the load and the store to achieve nearly one assignment per machine cycle.

2. The effects of cache are visible, just as they were for the IBM 3090; but the NAS XL's vector performance decreased more than the IBM 3090's for long vectors, probably due to the NAS XL's maximum performance being higher. Interestingly, the performance without cache (i.e., for the very longest vectors) of both machines was about the same.

Strangely, the vector length at which cache degradation began was not the same for the hand-coded and the machine-generated code. Since they both ultimately used the same machine op-code, this difference is at first sight puzzling; it seems to be due to details of the cache replacement algorithm, which depend on the real address of the data. On different runs, the MVS operating system (which employs virtual addressing) presumably mapped the arrays to different real addresses, causing some variation in the maximum working set size permitted by the cache replacement algorithm.

3. On the standard (rolled) scalar loops, the NAS XL achieved about the same performance as the IBM 3090, as one might expect from their nearly identical cycle times. But there was a surprise:

4. The NAS XL exhibited much greater performance improvement on loop unrolling than did the IBM 3090. Rolled scalar loop performance reached 9 MOPS on the NAS XL, whereas its unrolled scalar loop performance reached 23 MOPS, higher than the Cray's unrolled performance, more than a factor of two above the IBM 3090's unrolled performance, and in fact higher than the 3090's vector performance! Since both the NAS XL and the IBM 3090 have nearly the same cycle times, one must conclude that the NAS XL's scalar processor is capable of more instruction overlapping--and this capability apparently becomes evident when branches do not interfere with the machine's pipelining.

5. Like the IBM 3090, the NAS XL achieved 50% of its maximum scalar performance with very short loops: five or less. This good scalar performance on small loops is in sharp contrast to the Cray's scalar overhead, as mentioned above.

6. As was the case for both the Cray and the IBM 3090, the NAS XL required long vectors to achieve its maximum performance--vector lengths in the range 500 to 2,000. Half of the maximum was obtained between 30 and 100 (depending on the method of code generation). Vector break-even occurred for vectors of length 5 to 20 for rolled scalar code, and 20 to 70 for unrolled scalar code.

Overall, the most startling result of the vector assignment test may have been the scalar results: two machines with nearly identical cycle times (the IBM 3090 and the NAS XL) exhibited such drastically different performance; and the NAS XL's scalar processor was faster than the Cray's, which had half the NAS XL's cycle time. It is evident that the architectures of these three machines are very different.

In conclusion, even though the assignment test might not appear to measure anything "useful" (one hardly buys a vector processor to move data from one storage location to another), it nevertheless conveys much useful information, such as:

* The ability (or lack thereof) of the vector processor to "chain" operations;

* The extent of the scalar processor's pipelining capability;

* The ability of the vector processor to approach the theoretical maximum performance derived from its cycle time;

* The minimum vector length required for the vector processor to surpass the scalar processor's performance (i.e., the "vector break-even length");

* The problems that some machines encounter with cache degradation for long vectors.

These factors will now be described for arithmetic operations.

3. VECTOR MULTIPLY

The previous section's discussion of the "Vector Assignment" test was very long, since it included many descriptions of vector and scalar processing issues, along with a discussion of the way the graphs in this paper present data. With that background now established, the sections describing the other vector tests can be much shorter. This section describes the "Vector Multiply" test.

By contrast with the vector assignment test, the vector multiply test actually performs some "useful" work: REAL*8 multiplies. The test times the following FORTRAN loop (or its unrolled or vectorized equivalent):

```
      DO 3 i = 1, N
3     X(i) = Y(i)*Z(i)
```

Figure 3 presents timing data from a Cray, an IBM 3090, and an NAS XL. The main points to observe are:

1. Figures 3 and 2 are quite similar. In particular, both the Cray and the NAS XL achieved about the same vector performance on multiply as on assignment, indicating that both machines are capable of vector chaining. That is, adding an additional memory reference and a multiply made little or no difference in the execution time! That startling result illustrates the power of vector chaining.

2. The IBM 3090's vector processor, however, slowed to somewhat less than one operation in three machine cycles, indicating that it does not chain--the load, multiply, and store operations are not overlapped and proceed sequentially.

3. Loop unrolling significantly improved both the Cray's and the NAS XL's scalar performance, but had little effect on the IBM 3090's; this result was similar to the vector assignment test (Figure 2). A closer comparison of Figures 2 and 3 shows that for all three machines, unrolling the multiply loops had less effect than unrolling the assignment loops. This result is easy to understand--the multiply test has more instructions in its scalar loop, decreasing the loop overhead (and increasing the pipelining) for the scalar loop. Therefore, the multiply loop is more efficient than the assignment loop, so unrolling yields less (but still significant) performance improvement.

Apart from those differences, the results shown in Figure 3 are remarkably similar to those of Figure 2; again, the NAS XL scalar performance on unrolled loops was about the same as the maximum IBM 3090 vector performance, and preserved its peak value to much shorter vectors. Also, the Cray's scalar processor required by far the longest "vectors" to reach 50% of its maximum performance.

4. VECTOR ADD

The vector add test times the following construct:

```
            Do 4 i = 1, N
4           X(i) = Y(i) + Z(i)
```

The results from the vector add tests are reproduced in Figure 4. They were essentially identical to those from the vector multiply. This important result should be stressed --vector adds and vector multiplies took the same time on the three machines tested. This performance equality exists whether or not the adder and multiplier are equally fast in scalar mode; the essential point of vector operation that should be clearly understood is that properly implemented pipelining produces one result per cycle, regardless of the length of the operation involved, providing that the vector length is large enough to overcome start-up effects. This form of pipelining within an arithmetic operation is sometimes called "segmentation" (particularly in CDC and Cray parlance).

Note that the scalar tests shown in Figure 4 were slightly faster on the IBM 3090 and the NAS XL than the scalar results of the multiply test (Figure 3); the adders on these machines are slightly faster than the multipliers, so that scalar adds go a bit faster.

5. VECTOR DIVIDE

At this point, the reader might be under the impression that all vector instructions proceed at the same rate, especially on machines with vector chaining. Unfortunately, such is not the case: divide operations present a serious problem to machine designers, since the divide operation does not appear to be segmentable (it is usually implemented as an iteration, thereby using the same hardware gates for several cycles). The ability to segment an arithmetic operation is crucial to vector performance, since without segmentation the processor is unable to deliver one operation per cycle and the advantage of vectorization is essentially lost.

Figure 5a presents timing data from the vector divide test, which times the following construct:

```
        Do 5 i = 1, N
5       X(i) = Y(i)/Z(i)
```

The figure shows that vector divide performance is drastically below that of the previous vector operations. Divide performance is so low that Figure 5b has been prepared with an expanded vertical scale (extending to 30 MOPS instead of 110 MOPS).

Figure 5b shows that loop unrolling only helped the Cray's scalar performance (perhaps because of the Cray's architectural differences mentioned above). On the IBM 3090 and the NAS XL, divide was such a slow operation that loop overhead was insignificant (so unrolling the loop did not materially reduce the overhead); and since the machines' divide instructions evidently could not be segmented, there was no pipeline improvement available to loop unrolling.

The machines' maximum vector speeds for divide were:

* Cray-XMP -- 4.7 cycles;
* IBM 3090-VF -- 20 cycles;
* NAS AS/XL -- 6 cycles.

Programmers frequently avoid divide instructions in order to improve performance. For example, "Gaussian Elimination", a technique often employed in matrix inversion, requires among other things that each row of the matrix be divided by the value of its first element. This "normalization" is usually accomplished by first inverting the first element, then multiplying by that inverse using either a scalar loop or a vector multiply operation. In that way, a vector divide (or a scalar loop full of divides) is avoided.

Machine designers frequently use hardware monitors to capture op-code frequencies; they therefore see few divide instructions, and conclude that divide is a rare instruction, so building a fast divider is unnecessary. The result may be a self-fulfilling prophecy: divide instructions remain slow and seldom used.

6. ADD UP A VECTOR

A frequent vector operation is summation--not the equivalent of a vector add, but rather summing the elements of a vector:

```
        SUM = 0
        Do 6 i = 1, N
6       SUM = SUM + X(i)
```

Summation is a component of the "Dot Product" operation, frequently used in engineering. As Reference 1 points out, summation or "Add up a Vector" is not truly vectorizable (in the sense of being able to pipeline one add per machine cycle) unless the complex technique of "partial sums" is used. With partial sums, vector performance improves at the expense of evaluating the summation in a different order, thereby possibly yielding a slightly different result. Figure 6 presents the measurement data from this test.

Figure 6 is different from the earlier tests in several ways:

1. The Cray results show the highest vector performance of any of these tests--110 MOPS, achieved using a partial sum number of eight (i.e., eight separate add chains; see Reference 1). This peak performance was obtained at a cost, however: 50% of the maximum was not obtained until the vector length reached 500, and performance was still rising at a vector length of 20,000! For more modest vector lengths, performance was considerably lower; at a vector length of 50, for example, only about 15 MOPS was obtained. But at that vector length, both the IBM 3090's and the NAS XL's scalar speed exceeded the Cray's vector speed!

Paradoxically, although the Cray achieved its highest performance on this test, the scalar speed exceeded the vector speed for vectors shorter than about 20.

2. The IBM 3090 results also showed that machine's highest vector performance--about 40 MOPS, almost twice the earlier maxima. This result was achieved by the hardware's partial sum mechanism, employing a partial sum number of four (i.e., four separate add chains). But unlike the Cray results, the IBM 3090 performance reached 50% of its maximum at the much more modest and achievable vector length of 70 (which was only slightly above the vector break-even length for unrolled loops). Note that at that vector length, the IBM 3090 performance exceeded the Cray's.

3. The NAS XL performance was also noteworthy in that the unrolled scalar loop performance was substantially better than the vector performance! The reason is twofold: (1) the NAS XL vector processor does not use partial sums, and (2) its adder is capable of operating once every 1.5 machine cycles. With a 1.5 cycle adder, a sufficiently unrolled scalar loop would be capable of 37 MOPS (which was achieved, as Figure 6 shows); but the vector processor, which can only issue instructions on cycle boundaries, was therefore limited to two cycles per add, yielding 28 MOPS (also achieved, as shown in the figure).

Because the NAS XL does not use partial sums, it does evaluate the summation in the order specified in the FORTRAN code. For some critical numerical computations, the order of summation may be important. For that reason, the Cray compiler has a directive that forces computations to proceed in the order implied by the FORTRAN source, and therefore eliminates vectorization of such operations as vector summation and dot product. The programs that require such treatment would also preclude vectorization on the IBM 3090, but could proceed without problems on the NAS XL.

Note also that for vectors shorter than about 200, the Cray was the slowest of the three machines measured.

7. DOT PRODUCT

The dot product construct is frequently encountered in engineering and scientific applications. It can be defined by the FORTRAN loop:

```
        DOTPROD = 0
        Do 7 i  = 1, N
7       DOTPROD = DOTPROD + X(i)*Y(i)
```

Note that "Add up a Vector" is an integral part of "Dot Product". Figure 7 presents measurement data on "Dot Product".

As was the case for the "Add up a Vector" test, the Cray joined the IBM 3090 and the NAS XL in that short vectors were faster in scalar mode. Also, the Cray required a very long vector (about 300) in order to achieve half its maximum vector performance. The performance difficulties of the "Add up a Vector" component of the calculation are evidently also inherent in dot product.

By contrast, the IBM 3090 approached its maximum vector performance at a vector length of about 200; 50% of maximum was achieved somewhere between vector length 20 and 50. Scalar loop unrolling did not assist the IBM 3090, and as above the Cray's scalar processor required much longer vectors than the other machines in order to reach 50% of its maximum rate.

Inquiries to Livermore disclosed that the Cray compiler generates a subroutine call to process dot product, thus encountering significant overhead. For some reason the NAS XL, using the VAST pre-processor (which also generates a subroutine call), did not encounter as much overhead, although the IBM architecture (which is implemented by the NAS XL for scalar instructions) is frequently criticized for its excessive overhead on subroutine linkage--and the Cray operating system is felt to be efficient at subroutine linkage.

When the vector length became long enough for the Cray to approach its maximum speed, it executed at about 95 MOPS, faster than any test other than "Add up a Vector". Yet dot product is more complex: for the Cray architecture, it requires two vector loads, a vector multiply, and a vector summation operation. Evidently all four operations were chained, so that they could proceed simultaneously in a single machine cycle. The Cray's dot product performance is an important illustration of a peculiar property: vector performance is less related to the complexity of the operation than to the characteristics of the machine's architecture.

The IBM 3090 achieved a maximum rate of somewhat more than one operation in three cycles--impressive performance for a non-chaining machine, considering that a load, a multiply, and a summation are required on that machine. Actually, there is an instruction "Vector Multiply and Accumulate" that internally chains the multiplier and the adder of the IBM 3090 (that is, the single op-code exercises both the multiplier and the adder in parallel) so that dot product, which can use that instruction, is optimized. Evidently the machine designers targeted dot product for special treatment.

The NAS XL designers also targeted dot product for special treatment by including a "Dot Product" op code. Nevertheless, full chaining was not achieved (since partial sums were not used); the instruction executed in one operation per two machine cycles.

Those who are interested in the metric "millions of floating point operations per second" (MFLOPS) should note that, because dot product includes both a multiply and an add, the MFLOPS rate is twice the MOPS rate reported here. The maximum MFLOPS rates for the three machines were thus about 185 (Cray), 40 (IBM 3090), and 55 (NAS XL).

8. SCALAR*VECTOR + VECTOR

As mentioned in Reference 1, this set of operations is frequently encountered in matrix inversion codes. The following FORTRAN loop describes these operations:

```
      Do 8 i = 1, N
8     X(i) = X(i) + A*Y(i)
```

Where X and Y are vectors as above, but A is a scalar.

This test should be especially interesting to CPE analysts since it comprises the bulk of the LINPACK performance test (Ref. 3); many "engineering/scientific" customers are heavily influenced in their acquisitions by LINPACK performance figures.

The results of the "Scalar*Vector + Vector" test yield exactly the same information as the LINPACK benchmark--more in fact, since LINPACK is usually run only for a few vector lengths (lOOxlOO and 300x300 are the typical matrix sizes). Figure 8 presents the results of these tests. Like dot product, "Scalar*Vector + Vector" contains both a multiply and an add, so its MFLOPS rate is twice the MOPS rate reported in the figures.

The NAS XL was almost as fast as the Cray on this test. The NAS XL's designers also targeted this operation for optimization: they implemented "Scalar*Vector + Vector" as a single machine op-code, with chaining. This peculiarity of the NAS XL hardware demonstrates the fallacy of using this test (or the LINPACK benchmark, which is the same thing) as the sole measure of vector performance: the relative performance of the three machines is thereby presented in a distorted light. Compare the graphs of Figure 8 with the other figures; Figure 8 is atypical in two important respects:

1. The Cray's maximum rate was about 70 MOPS, the lowest of all the Cray vector performance figures;

2. The NAS XL had a special instruction to perform this test, making its performance about 53 MOPS, about equal to the highest of any NAS XL vector performance figure and about 80% of the Cray's performance.

Yet an entire school of thought bases relative machine performance on this test (see, for example, the recent IEEE Spectrum article of Reference 5).

9. LONGER EXPRESSION (ADD, MULTIPLY, ADD, MULTIPLY)

The previous tests have been fairly simple operations chosen because they are probably widely used as components of vector codes. But in real applications, the vectorizable loops may be much more complicated, consisting of several vector operations. What is the performance of more complicated constructs? This test is designed to find out:

```
      Do 9 i = 1, N
9  X(i) = A(i)*(B(i) + C(i)*(D(i) + E(i)))
```

The test uses four operations (two multiplies and two adds) sequentially; that is, each addition and multiplication requires the results of the previous ones. The graphs in Figure 9a show MOPS as before; the MFLOPS rate is now four times the MOPS rate, since there are four floating point operations in each computation of X(i). Figure 9b has been prepared with an expanded vertical scale, since the MOPS rates were low on this test.

With the information gleaned from the previous tests, it should be possible to predict some features of the performance of this test. For example, one would expect that:

1. Scalar loop unrolling should help much less than for the previous tests, since this test includes more computation per result (and therefore a rolled scalar loop will have more instructions per loop);

2. Vector performance should be significantly better for machines capable of more vector chaining.

Quantitatively, the number of cycles per completed X(i) (i.e., the peak vector performance) should be:

Cray--capable of chaining two loads, one store, one add, and one multiply:

Cycle 1: Load D; Load E; Add

Cycle 2: Load C; Multiply: Load B; Add

Cycle 3: Load A; Multiply; Store

Thus the maximum rate should be one result in three cycles, or 39 MOPS. Since there will be some sectioning overhead, the results of Figure 9 (about 30 MOPS) are consistent.

IBM 3090--With no chaining, this machine's performance is easy to calculate; each of the following instructions requires one cycle:

Load D;
Add E;
Multiply by C;
Add B;
Multiply by A;
Store to X.

--for a maximum rate of one result in six cycles, or 9 MOPS. With some sectioning overhead, the result of about 7 MOPS is in agreement.

NAS XL--The chaining capability of this machine is intermediate between that of the Cray and the IBM 3090. The situation is actually more subtle than described above, as follows: the NAS XL's vector processor chains only within an instruction (this might be called "intra-instruction" chaining, as opposed to the Cray, which has "inter-instruction" chaining). Since NAS XL vector instructions are memory-to-memory, and the instruction set is fairly rich, each of the above tests could be implemented as a single vector instruction. Therefore the "intra-instruction" chaining usually resulted in a maximum processing rate of one complete operation per machine cycle.

The IBM 3090 also has "intra-instruction" chaining, but since its instructions are more "atomic" in nature, the above tests usually translated into two or three IBM 3090 vector instructions, with lower resulting performance.

The Cray has even more atomic instructions than the IBM 3090, but its full "inter-instruction" chaining more than makes up for the difference.

Returning to the calculation of NAS XL vector performance: Test 9 can be implemented as follows on an NAS XL, with one instruction per cycle:

Add D and E;
Multiply by C;
Add B;
Multiply by A.

--for a maximum vector rate of one result in four cycles, or 14 MOPS. Since there is no sectioning overhead on an NAS XL, that rate was actually achieved.

Test 9 therefore illustrates very important chaining properties of the machines tested. For example, one conclusion is that even though the IBM 3090's architecture (with vector registers) is much more like the Cray's than is the NAS XL architecture, the NAS XL nevertheless is much closer to the Cray's performance by virtue of more extensive use of chaining.

Test 9 also yields some important scalar information: the Cray scalar processor was able to benefit significantly from loop unrolling, contrary to expectation (whereas the IBM 3090 and NAS XL scalar processors were virtually unaffected by loop unrolling). Another way to view this result is that the Cray scalar processor's performance is much more susceptible to damage due to looping than either the IBM 3090's or the NAS XL's. As before, the Cray's scalar performance was poor for very short "vectors": it reached 50% of its peak unrolled performance at a length of about five, whereas the other two machines were above 50% of their peak performance even when only one operation was performed.

10. ARCHITECTURAL CONCLUSIONS

The above data suggest the following observations:

1. Vector performance is less related to the complexity of the operation than to the characteristics of the machine's architecture.

2. Machines with vector chaining (e.g., the Cray-XMP and the NAS XL) have substantially better vector performance than non-chaining machines (e.g., the IBM 3090).

3. The Cray's vector performance is considerably better than that of either the IBM 3090 or the NAS XL; in particular, the Cray achieves "vector break-even" at much smaller vector lengths than the other machines.

4. By contrast, the Cray's scalar processor seems quite inferior to those of the other two machines. Not only does the Cray's scalar performance suffer for small "vector lengths", but loop unrolling improves its performance even for the most complex operations. Looping seems to seriously degrade the Cray's scalar performance, compared to the other machines tested.

5. Both cache machines (the IBM 3090 and the NAS XL) degrade substantially when the data will not fit in cache. Although one might argue that vector lengths of several thousand (the size where the problem starts) are rare, the cache degradation problem may also be present for matrix operations; even modest-sized matrices may exceed several thousand elements.

6. Roughly speaking, the Cray has an impressive vector processor, and the IBM-style machines (especially the NAS XL) have impressive scalar processors. A machine incorporating the best of both might seem desirable, but in fact it might suffer from inadequate vector performance.

11. SUGGESTIONS FOR FRUITFUL VECTORIZATION

The data in this paper have shown that adequate vector lengths are mandatory in order to achieve a benefit from vector processors. The following discussion is therefore included:

11.1 VECTOR LENGTH

It is overwhelmingly important to know what vector lengths occur in actual practice. Livermore reports that they have measured their average vector length to be about 70 (Ref. 4). With such short vectors at an installation that would seem to be the preeminent vector user, one wonders what less auspicious vector lengths occur in the rest of the world. There appear to be almost no data available on this subject, although there are three reasons why vector lengths may be small in practice:

1. Many engineering and scientific applications use two- and three-dimensional matrices in their calculations. Nevertheless, many vector algorithms process only a row (or column) of a matrix at a time, so that a 70x70 matrix would generate a vector length of 70, not 4,900. And a three-dimensional 70x70x70 matrix contains 343,000 elements requiring 2.7 megabytes on an IBM-style machine, but probably still uses a vector length of only 70. Clearly not many such matrices will fit in memory; larger matrices (for longer vectors) require even more memory.

2. Livermore also reports that applications that perform physical simulations are frequently CPU-bound rather than memory-bound; for example, a three-dimensional grid of points spanning some physical system of interest. If the simulation is to be improved by, say, doubling the number of simulated points per inch (thereby increasing the required storage by a factor of eight), not only will the CPU time per complete calculation be multiplied by eight, but also the required number of time steps will be doubled. This additional doubling is caused by the fact that effects at one grid point will reach the next grid

point in half the time of the old simulation (the grid points are now half as far apart). So to simulate the same amount of physical time, the CPU time will increase by a factor not of eight, but rather of 16. Thus, paradoxically, the limit on vector length for physical simulations may not be storage, but rather CPU time.

3. Some operations on NxN matrices do not even have vector lengths as large as N. For example, matrix inversion generates upper-triangular matrices and processes them-- thus, the vector length will run uniformly from 1 up to N. Short vectors therefore appear to be unavoidable in real applications, no matter how large the matrices.

For all these reasons, vector lengths may be disappointingly small in practice (or more properly, result in disappointing performance).

Consider the data in Figures 1 through 9. Even though the Cray vector processor was always the best peak performer, at a vector length of 70 most of its advantage disappeared. For example, on the "Scalar*Vector + Vector" test the NAS XL vector processor was almost equal to the Cray's vector processor; for "Dot Product", the IBM 3090's vector processor was about as fast as the Cray's, and the NAS XL was faster; and finally, on "Add up a Vector", the IBM 3090's scalar processor was about as fast as the Cray's vector processor, and the NAS XL's scalar processor was almost twice as fast as the Cray's vector processor! (Remember that these comments are specific to a vector length of 70.)

For many applications, therefore, scalar processors provide performance as good as (or even better than) vector processors--despite a recent claim in the literature that "scalar machines have been made largely obsolete" (Ref. 5).

The results presented above suggest a number of guidelines for those who will be writing code for vector machines:

1. Above all, long vectors are required for adequate vector performance--indeed, they may be necessary to keep vector performance from being worse than scalar performance.

   a. Try for vector lengths in the hundreds or even thousands.

   b. In matrix calculations, try to vectorize a plane rather than a row. Considerable success has been reported using such techniques in special cases (Ref. 4).

   c. Use scalar operations, especially unrolled loops, where vector lengths are short. The benchmark technique reported in this paper can be used to determine what "short" means.

2. Take advantage of vector chaining where your architecture permits it.

3. For cache machines, note the limitations on vector length for good performance.

4. Avoid vector divides.

12. SUGGESTIONS FOR FUTURE VECTOR PROCESSORS

The data presented above also suggest ways in which future vector processors can achieve better performance than now available:

1. Vector processors need greatly reduced start-up times, in order to reduce the "vector break-even" lengths--which for some instructions on some machines approach the reported average vector length.

2. It appears that a vector register length of 64 (as used by Cray) limits performance. Even 128 (as used by IBM) may not be long enough. Longer vector registers are indicated.

3. Vector chaining is mandatory for good vector performance. It is especially important for register machines, since otherwise each required load and store consumes one additional machine cycle per operation. For example, the NAS XL scalar processor is frequently as fast as the IBM 3090 vector processor (a vector register machine without chaining)--yet both machines have essentially the same cycle time.

4. Cache machines may need larger caches, or some way to circumvent effects due to cache degradation.

5. Vector performance analysis tools are sorely needed. Particular emphasis should be given to reporting vector lengths, overhead involved in vector processing, and percentage of time spent executing in vector mode.

13. CONCLUSION

The benchmark technique discussed in Reference 1 has been used to produce information on vector vs. scalar performance architecture of the three machines tested: a Cray-XMP/416, an IBM 3090-200/VF, and an NAS AS/XL VIOO. The main lessons can be summarized as follows:

1. Vector performance may be worse than scalar performance for short vectors--sometimes "short" is as long as 70 elements;

2. Very long vectors (hundreds or even thousands) are required to approach the limits of vector performance;

3. The amount of vector chaining varies substantially among the available vector processors. Chaining dramatically improves vector performance by allowing several instructions to complete in every machine cycle;

4. Loop unrolling can provide significantly improved scalar performance, especially on heavily pipelined machines. The performance of unrolled loops in this benchmark is probably equivalent to that of real applications with several operations in a loop.

The data have also been analyzed to produce some simple guidelines for implementing vectorized code, and suggestions for future hardware improvements to vector processors.

CMG attendees are invited to run this benchmark free of charge, provided only that they return data to the author so that more information can be gathered on today's processors. It is not necessary to run the benchmark on a vector processor--as mentioned above, interesting data are produced even for scalar processors. At the end of the paper is a request form for a copy of the vector benchmark.

14. ACKNOWLEDGMENT

The author wishes to thank Frank McMahon of Lawrence Livermore National Laboratory, who ran the benchmarks on a Cray-XMP and supplied the Cray results that appear in this paper; suggested loop unrolling; and originated the analysis of vector length that is presented in Section 11.0 of this paper.

BENCHMARK REQUEST FORM

Name _____

Company _____

Address _____

City/State/Zip _____

Telephone (___)_____

I was an attendee at CMG-87. I enclose a 51/4" floppy diskette for a copy of (1) the FORTRAN source for the Vector Architecture Benchmark, (2) the input file, and (3) instructions.

In return for these I agree to provide within 30 days:

1. Execution times for at least one computer. NOTE: It is not necessary to run this benchmark on a vector processor;

2. Information about test conditions including (at least):
   a. Whether stand-alone or normal production run;
   b. Job priority;
   c. Machine model and characteristics (e.g.,memory);
   d. Compiler and version;
   e. Whether vector or scalar. For scalar, unrolling level;
3. Listing of timer routine used if not already in benchmark source;
4. Permission to report these data.

I understand that future versions of this Vector Architecture Benchmark may include the names of individuals who fail to meet this agreement, and I would welcome such public exposure should I fail to provide the agreed materials within 30 days.

A TECHNIQUE FOR EVALUATING THE PERFORMANCE OF VECTOR PROCESSORS

Dr. David S. Lindsay
National Advanced Systems

ABSTRACT

With the advent of vector processors on general-purpose machines such as the IBM 3090, vector processing has emerged from the scientific arena and become a topic of interest to large systems users in general. Performance analysts at traditionally "general purpose" sites have begun receiving requests to analyze the performance of such processors.

This paper presents a technique for investigating the performance of vector processors, a technique that yields such vital information as the vector break-even length, the ability of the processor to chain, and, for cache machines, the performance implications of referencing data that are not in cache. The technique also yields much information about the underlying architecture, giving rise to a benchmark called the "Vector Architecture Benchmark". A companion paper (Ref. 1) presents results of this benchmark on some of the most widely used vector processors.

1. INTRODUCTION

Analyzing vector processing is a "natural" for performance analysts, since there is only one reason for vectorization: performance. A CPU gains no new functionality by acquiring a vector processor; anything that can be done by a vector processor can easily be done by a scalar processor--more easily, in fact, since traditional methods and programming languages can be used in scalar mode. The only justification for an expensive vector processor is speed.

Unfortunately, the performance of vector processors is more fragile than that of general purpose processors: dramatic (factor of 10) speed improvements are possible, but vectorized programs can also run slower than equivalent scalar programs. Performance immediately becomes an issue when a data center is asked to justify the acquisition of a vector processor. Thus, it is essential for CPE professionals in vector installations to become cognizant of the deficiencies and opportunities inherent in vector processing.

Before exploring methods of evaluating the performance of vector processors, it is important to understand how vector processing works and under what circumstances good and bad performance should be expected.

1.1 OVERVIEW OF VECTOR PROCESSING

"Vector processing" refers to highly parallel processing. Vector processing includes the following characteristics:

1. Vector processors are usually designed for Engineering/Scientific" applications.

2. Special vector hardware is supplied with the CPU.

3. Special machine instructions are required to use the vector hardware. These in turn must be generated somehow--by the user writing his own programs in assembler language, by a special vectorizing feature of a high-level language compiler (usually FORTRAN), or by embedding (into regular source code) calls to a library of specially vectorized subroutines.

4. Vector processors usually execute floating point (i.e., the FORTRAN REAL data type), although many machines also have integer and logical vector capabilities.

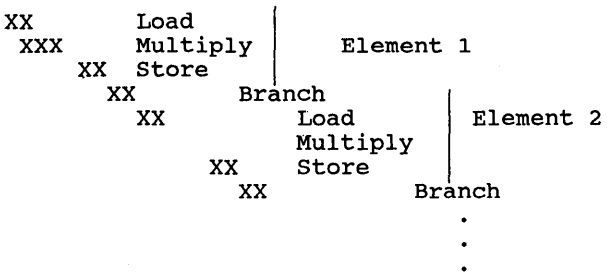
5. Vector instructions are usually simple instructions such as multiply, add, compare, etc.; complex instructions such as the COBOL "Edit" instruction are not available in vector hardware, and flow-of-control instructions such as branches are by their nature not vectorizable.

6. If the CPU in question has a memory cache, the vector instructions may or may not reference it (a cache is a small, high-speed auxiliary memory that is used to store the currently referenced code and data of a program. A cache is invisible to the programmer, being maintained by the CPU itself). Not all vector processors have caches; a Cray-XMP does not, whereas both an IBM 3090 and an NAS AS/XL do. If the vector instructions reference cache, vector performance may degrade if the associated data are not in cache. Possible reasons for data not being in cache are: (1) the application program has poor "locality of reference"; (2) many program interrupts have overwritten the cache; or (3) the vectors are too large to fit in the cache. CPU caches may therefore affect vector performance.

As an example of vectorization, consider the following FORTRAN DO-loop:

```
      DO 1 i = 1, N
1     X(i) = Y(i)*Z(i)
```

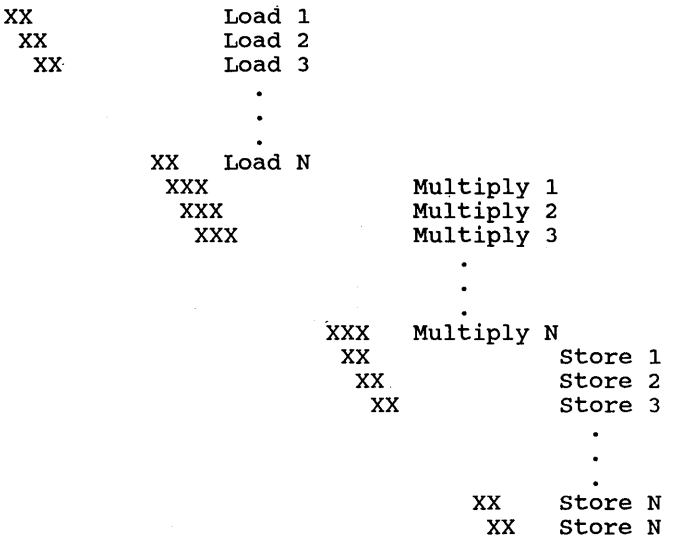
Where N is called the "vector length". On a scalar (i.e., non-vector) machine, the execution might proceed as shown in Figure 1, where the X's are meant to represent individual machine cycles consumed by the associated instruction. The number of X's is purely illustrative--whether multiplies actually take three cycles, and loads and stores two, is irrelevant to the current discussion. Those values are used in order to be specific about the timing computations. In the example of Figure 1, each instruction must complete before the next can start (e.g., you can't store a result that has not yet been generated); thus, the loop is doomed to consume several machine cycles (nine in this case) per multiply.



Timeline for Scalar Multiplies in a Loop
(Requires 9N cycles)

Figure 1

Using a vector processor, however, the same loop could be processed as depicted in Figure 2. The importance of Figure 2 is that the individual operations (load, multiply, and store) are each pipelined so that, as shown, a new operation can be started in each machine cycle. There is also some overhead involved in starting the vector instruction (e.g., the programmer or compiler must set certain values and pointers in registers, and the hardware may also take time to decode the vector instruction and start the vector processor).



Timeline for Vector Multiply
(Requires 3N Cycles + Start-up Time)

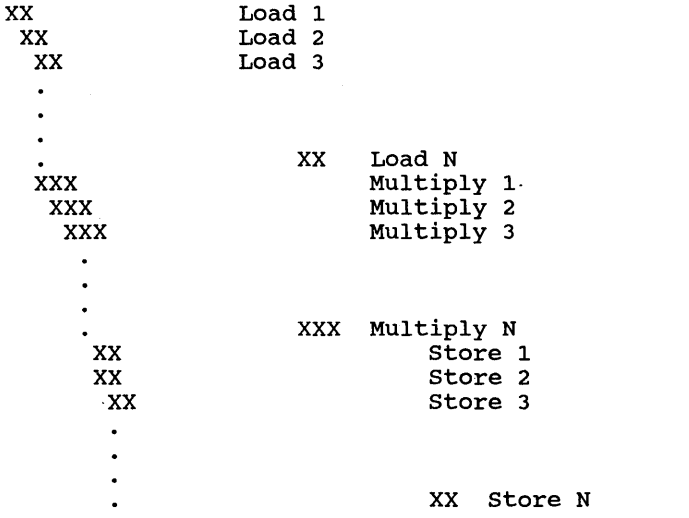
Figure 2

The number of repetitions of the basic instruction (in this case, the number of multiplies) is called the "vector length", N in this case. From Figure 2, one can easily see what makes a vector processor so attractive--in this example, the processing time is only 3N cycles plus the start-up time. Note that the value 3N is not dependent on the number of cycles required for a multiply or a load; it is a consequence of the pipelining of the three vector instructions (load, multiply, and store). The IBM 3090-VF is an example of a vector processor that operates as shown in Figure 2.

Therefore, if the vector length N is large enough to offset the start-up time, vector processing will be faster than scalar processing.

1.2 VECTOR CHAINING

There is another level of sophistication that can be implemented, as shown in Figure 3. This additional level is called "Vector Chaining", or just "chaining" for short. Chaining is possible because the first multiply could logically be started the moment the first load is complete--without waiting for the rest of the loads to complete, or even start. Similarly, the first store can begin as soon as the first multiply is complete. Figure 3 portrays these timing relations--the dotted lines indicate the conclusions of the first operations of each vector instruction.



Timeline for Vector Multiply With Chaining
(Requires N Cycles + Start-up Time)

Figure 3

Thus, if nothing interrupts the various pipelines, the loads, multiplies, and stores all proceed in parallel; the result is N multiplies in N cycles plus start-up time.

The hallmark of vector chaining is thus one full operation per machine cycle. This speed is independent of the actual number of cycles required for (say) a multiply; the point is that the load, multiply, and store are all overlapped and pipelined. The architecture permits one operation per cycle, regardless of the length of an individual operation.

Vector chaining is obviously a very powerful feature, since it means that many operations can be performed simultaneously. For example, a Cray-XMP is capable of chaining two loads, one store, one multiply, and one add (in addition to various other operations). This means that, once the vector units have been started, a Cray can execute those five operations in each machine cycle, potentially executing at many times the MIPS rate implied by its cycle time.

To summarize this overview of vector processing, it is helpful to refer again to the example of the vector multiply:

1. In scalar mode (which is what a normal programmer uses all the time), the execution proceeds in a loop, roughly as depicted in Figure 1. Using the timing example presented there, each multiply would consume nine machine cycles (a load, a multiply, a store, and a branch). Little or no overlap of successive instructions is possible.

2. Using a vector processor that is not capable of chaining, execution proceeds as shown in Figure 2; the execution time will be a constant start-up time dependent on the program and the processor (but not on the data or the vector length),

followed by three cycles per multiply.

3. Using a vector processor that is capable of chaining, the processing time will be some other start-up time, again independent of the data or the vector length, followed by only N machine cycles.

1.3 PERFORMANCE DEFICIENCIES OF VECTOR PROCESSING

The above discussion has noted that some "start-up time" is consumed by a vector processor. This time is potentially disastrous from a performance viewpoint: if the vector length is not long enough to compensate for the start-up time, the vector instruction will be slower than the analogous scalar loop, regardless of how fancy (and expensive) the vector hardware is. This problem is real: the companion paper (Ref. 1) includes many examples where a vector length of 20 to 50 is required before a vector processor achieves the same performance as the scalar processor. Longer vectors are required to exceed scalar speed.

One can see that the performance of a vector processor is more fragile than that of a standard processor. In addition to all the usual performance pitfalls, vector processors are subject to:

1. Poor performance on short vectors.

2. Cache machines may degrade for long vectors if the cache size is exceeded. Such cache degradation may be more pronounced in vector mode than in scalar mode, because the vector speed is generally faster than the scalar speed.

3. If vector chaining is not implemented in the hardware, the vector/scalar performance ratio will decrease as the complexity of the vectorized expression increases; but if chaining is present,then the vector/scalar performance ratio can improve with increasing complexity.

The analysis approach described below allows a CPE professional to gain insight into how these and other effects influence the vector performance of a machine.

2. PREVIOUS BENCHMARK TECHNIQUES

Apart from some early work designed to determine the details of cycle-by-cycle machine execution (Ref. 2), most studies have ignored the details of vector processing. For example, the following techniques have recently been published:

1. Run a job, get a CPU time (Ref. 3).

This is a particularly uninformative test, since many important effects are ignored:

* The percentage of vectorized code is unknown.

* The vector lengths of the data are unknown.

* No insight is gained into vector performance--this technique is a pure "black box" with no windows. One can conclude at most that such-and-such a program took some time in scalar mode, another in "vector mode"--but can the compiler be improved ? Would slightly different data (with perhaps different vector lengths) yield drastically different performance? What about performance on other programs? Almost nothing of general applicability is learned from such a test.

2. Run a standard, vectorized package such as LINPACK using various vector lengths (Ref. 4).

This technique is marginally superior to the first technique, since something is being varied from one measurement to the next; but what? In the case of LINPACK, one actually sets a matrix size. What relation does this have to vector length? Only those intimately familiar with the package would know.

Another property of LINPACK is that it executes only a tiny subset of the available vector instructions--in the case of the vectorized LINPACK code that was run at NAS, there were only three different vector op-codes in the entire source. Such a small subset of the available instructions could easily yield a misleading idea of the vector performance of a machine.

Also, as was the case with method 1, the percentage of vectorized code remains a mystery. One might assume that it is 100% for a mathematics package like LINPACK, but is it really?

3. Run kernels from longer jobs, e.g., the Livermore Kernels (Ref. 5).

This technique is a considerable improvement over the previous ones. The Livermore Kernels contain 24 code fragments, each at three different vector lengths, every one of which is separately timed; the code in each timing loop is known, and the vector lengths are roughly stated in the tests' output. This benchmark is likely to yield a good idea of the spread in performance that real applications will exhibit--but it does not tell why.

A significant shortcoming of all of the techniques listed above is that they give no indication of the potential for improvement. Would performance improve if the vector lengths were increased? If so, how much? What vector lengths should new applications have for optimal performance? How about vectorization--was each loop fully vectorized? Might the next version of the compiler provide better performance? Is the current code optimal, so that nothing better can be obtained? Are some vector instructions much faster than others, so that certain instructions are to be preferred or avoided?

Because of the significant deficiencies inherent in existing techniques, a different philosophy was adopted for a vector benchmark, one that yields insights into the reasons for performance benefits and deficiencies. The technique is an outgrowth of earlier work on scalar machines (Ref. 6).

3. REQUIREMENTS FOR AN INFORMATIVE VECTOR BENCHMARK

Early in the study of vector performance at NAS, it became clear that there were significant issues that were either unique to vector performance or dramatically more important for vector code than for scalar code:

1. Vector speed vs. vector length;

2. Vector vs. scalar performance;

3. Sensitivity to data caching;

4. Ability to chain.

This list is not exhaustive, but it represents a necessary first step. Without a clear grasp of these issues, a CPE analyst faced with a vector processor is merely fumbling in the dark.

As mentioned above, an important parameter for a vector processor is the "vector break-even length". The approach described below measures that length (as well as many other important parameters) for a variety of vector instructions. The approach taken for the vector benchmark was:

1. Measure CPU time for several "atomic" vector instructions (such as "add", "move", "multiply", etc.).

2. Use vector lengths from 1 to 200,000, thereby (hopefully) spanning the entire range of sizes of most machines.

3. Insure 100% vectorization by including only a vector operation (or its analogous scalar loop) in the timing data. With the results of this test, one can easily compute the performance of partial vectorization. But if one only knows that "some" of the code was vectorized, of what use is the resulting performance figure?

4. Minimize measurement overhead and variability by carefully designing the timing technique.

In order to eliminate CPU measurement overhead from the timing data, the following technique (suggested by Dr. Tom Bell) was used:

```
Get CPU time;
      Execute 20 identical vector
      operations;
Get CPU time;
      Execute 40 identical vector
      operations;
Get CPU time;
```

By taking the difference between the two resulting time intervals, one neatly subtracts the overhead involved in calling the CPU clock, thereby yielding a nearly pure CPU time for 20 vector operations. In addition, other common elements in the code also cancel (so that, for example, the vector operations can be placed in subroutines for improved code modularity and readability without affecting the resulting timings).

Unfortunately, a problem arises for short vectors: the CPU times may be so small that the system's CPU timer does not give adequate resolution. That problem can be solved by looping, as follows:

```
Get CPU time;
      Do several times:
        Execute 20 identical vector
        operations;
Get CPU time;
      Do several times:
        Execute 40 identical vector
        operations;
Get CPU time;
```

Because the method of subtracting the two time intervals eliminates common factors, the additional overhead for setting up the "several times" loops is not measured. Only the branch and loop control times appear in the resulting measurement, and they will be both (a) small in comparison with the body of the loops, and (b) the same whether vector or scalar code is used for the "vector operations", so that the vector break-even point will not be affected. (One must of course remember to divide the resulting CPU times by the value of "several" that is used in the loop.)

The effects of cache can be determined by inspecting the timing data for various vector lengths. Because the vector operations are repeated, the data will be in cache as soon as the first pass is complete. In fact, the operations are usually repeated thousands of times; therefore, the resulting time per vector operation will be almost uncontaminated by cache misses, so the timings will refer to 100% in-cache data. But when the vector length is long enough, the data will not fit in cache, and the times may suddenly reflect 100% cache misses. Thus, a plot of MIPS rate versus vector length reveals the effect (if any) of cache misses (Ref. 1), and will give an indication of what can be expected if a real program executes in or out of cache.

The data type REAL*8 (i.e., double precision floating point) was selected for use throughout the benchmark, since most vector users report that double precision is required for their applications. The Cray-XMP, one of the machines for which data are reported in the companion paper, has 64 bit words, and REAL*8 is its natural mode; Cray users refer to 32-bit floating point as "half precision".

The individual vector operations that are timed in the vector benchmark are listed below. The FORTRAN code comprising the test loop is shown in each case; this code was compiled for the scalar tests, and passed through pre-processors, vectorizing compilers, or used as a model for assembler hand-coding in the vector cases.

These particular tests were chosen because of their "atomic" nature. Also, they include the commonly used operations--most calculations will be composed of sequences of these instructions:

1. Vector Assignment

```
        Do 100 i = 1, N
100     X(i) = Y(i)
```

This test was included since the only arithmetic it performs is for looping. Thus any performance effects due to floating point arithmetic speed will not be present. The test therefore shows the "raw" speed of the vector processor--an essential performance figure for adequate understanding.

2. Vector Multiply

```
        Do 200 i = 1, N
200     X(i) = Y(i) * Z(i)
```

In machines with chaining, the multiply instruction should execute at the same rate as the assignment instruction of Test 1, apart from a potentially different start-up time. Comparing the two instruction rates on long vectors will therefore show whether the vector processor in question is capable of chaining.

3. Vector Add

```
        Do 300 i = 1, N
300     X(i) = Y(i) + Z(i)
```

In a properly designed vector machine, both multiply and add should take exactly the same time, apart from start-up effects. Some readers might be surprised at that statement; but consideration of Figures 2 and 3 above show that the time for vector processing is independent of the operation performed, so long as the operation can be pipelined. Test 3 was included to demonstrate that feature of vector processing.

4. Vector Divide

```
        Do 400 i = 1, N
400     X(i) = Y(i) / Z(i)
```

Having just stated that most vector instructions execute at the same rate, it is important to realize that divide is an exception. This benchmark has encountered vector divide instructions ranging from slightly under five cycles per divide (Cray-XMP) to 20 cycles per divide (IBM 3090-VF) (Ref. 1). The problem with divide appears to be that the instruction cannot be pipelined.

By inspecting the instruction rate of the divide test, one can determine how much of a performance penalty is incurred by divide operations.

5. Vector Summation

```
        SUM = 0
        Do 500 i = 1, N
500     SUM = SUM + X(i)
```

Summation (adding up the elements of an array, rather than adding two arrays together) is very useful as a component of the vector "dot product" operation and in other applications. Naively, one would expect that "summation" could not be vectorized: in an expression like X(l) + X(2) + X(3), the addition of X(3) cannot start until there is something to add it to--until the first add has completed.

This naive approach is both right and wrong: if one views the summation as specifying the order of the additions, vectorization is not possible. But if reordering is permissible, then the summation can be divided into two chains, as follows:

```
X(1) +    X(3)  +      X(5)   +     . . .
     X(2) +     X(4)    +      X(6)  . . .
```

If this reordering of the additions is acceptable (which it may not be, since the result of a series of floating point adds will in general be slightly different if the order of summation is changed--round-off errors may accumulate differently), the chains can be alternated in the adder, and it is no longer the case that each add must complete before the next can start.

When both chains are complete, two numbers remain; a single scalar addition then completes the summation. This is the technique of "Partial Sums", and is used on the Cray-XMP and the IBM 3090-VF. Actually, the summation is usually divided into more than two independent chains. For example, the IBM 3090-VF uses four chains, and the Cray-XMP uses eight.

Inspection of the timing data from Test 5 will show whether a "partial sum" technique is being used, since an execution rate of one add per machine cycle is generally not possible without partial sums.

6. Dot Product

```
        DOTPROD = 0
        Do 600 i = 1, N
600     DOTPROD = DOTPROD + X(i)*Y(i)
```

The "dot product" operation (more formally called "inner product") is very important in physics and engineering problems; a popular belief is that dot product is the most common vectorized construct.

Since dot product necessarily uses the summation function, it is interesting to compare the speeds of Tests 5 and 6. Not only will the results of this test provide execution times on a useful and probably frequent operation, it will also tell whether a multiply can be chained with whatever method the machine designer has chosen to implement the summation function.

7. Scalar*Vector + Vector

```
        Do 700 i = 1, N
700     X(i) = X(i) + A*Y(i)
```

Although Test 7 may seem artificial, it is included because it is frequently used in matrix inversions and multiplications. It is sometimes called a "SAXPY" operation (or "DAXPY" in the double precision case). Also, the LINPACK benchmark appears to spend most of its time executing code identical to Test 7; comparison of Test 7 with the other tests above can thus be used to gauge the validity of the LINPACK numbers as a guide to processor performance.

8. Longer Expression (Add, Multiply, Add, Multiply)

```
        Do 800 i = 1, N
800     X(i) = A(i)*(B(i) + C(i)*(D(i) +E(i)))
```

With several different vector architectures available (including register to register, memory to register, memory to memory, and perhaps others), a processor's efficiency on a simple vector instruction may not directly indicate its performance on a long series of vector instructions. The purpose of Test 8 is to investigate a processor's efficiency on a more complicated expression than those above.

Some machines have single op-codes to perform most (or all) of tests 1 through 7; but none (to our knowledge) has a single instruction to implement the above expression. Inspection of the resulting instruction rates can determine whether a processor's chaining ability extends to more complex situations.

4. SCALAR LOOP UNROLLING

The scalar FORTRAN loops presented above are by their nature somewhat inefficient, since they have considerable loop overhead compared with the very simple (and fast) constructs that they contain. Tests 1 through 3 may be particularly inefficient. The technique of Loop Unrolling has long been used (primarily on scalar machines) to reduce the loop overhead in such situations, especially in the scientific programming community. For example, the vector multiply operation (Test 2 above) can also be written as:

```
        Do 200 i = 1, N, 2
        X(i) = Y(i)* Z(i)
200     X(i+l) = Y(i+l) * Z(i+l)
```

Where N must now be a multiple of two. The loop performs two multiplies at a time, thus cutting the overhead per operation in half (and in addition producing more efficient operation on pipelined machines).

"Loop unrolling" can obviously be implemented with more operations per loop--4, 8, and even 16 appear in some scientific applications. The vectorized code, however, remains exactly the same, since the functions of the loops are identical. Thus comparing vector performance with with the performance of unrolled scalar loops will show the scalar processor in a more favorable light. One would probably expect that Test 1 above would benefit most from loop unrolling, and that Test 8 would benefit least.

Is this favorable view of scalar performance realistic? In most cases, yes: even when the applications being considered for vectorization have not been coded with unrolled loops, using unrolled loop times in this benchmark is nevertheless valid--because very few application programs have only one operation in a loop. In real-world programs, which have complex loops, there is naturally less loop overhead per useful operation--and, therefore, a benchmark having unrolled loops will more accurately reflect reality.

For those reasons, the benchmark reported herein has been developed not only with pure scalar loops like those shown in Tests 1 through 8, but also with each test unrolled with 2, 5, and 10 iterations per pass. (Those unrolling depths were chosen rather than the more traditional powers of two because the vector lengths in the benchmark are 1, 2, and 5 times a power of 10). Interestingly, some machines show more scalar improvement with unrolled loops than do other machines (Ref. 1); therefore, the scalar tests provide useful information even on machines without vector processors.

5. CONCLUSION

With many performance problems unique to vector processing, it is imperative that CPE professionals in vector installations become aware of the implications of vector processing. The benchmark described herein appears as a necessary and very informative first step in that process.

CMG attendees are invited to run this benchmark free of charge, provided only that they return data to the author so that more information can be gathered on vector processors. It is actually not necessary to run the benchmark on a vector processor; s mentioned above, interesting data are produced even for scalar processors. A request form for a copy of the vector benchmark is attached.

BENCHMARK REQUEST FORM

Name _____

Company _____

Address _____

City/State/Zip _____

Telephone (___)_____

I was an attendee at CMG-87. I enclose a 51/4" floppy diskette for a copy of (1) the FORTRAN source for the Vector Architecture Benchmark, (2) the input file, and (3) instructions.

In return for these I agree to provide within 30 days:

1. Execution times for at least one computer. NOTE: It is not necessary to run this benchmark on a vector processor;

2. Information about test conditions including (at least):
   a. Whether stand-alone or normal production run;
   b. Job priority;
   c. Machine model and characteristics (e.g.,memory);
   d. Compiler and version;
   e. Whether vector or scalar. For scalar, unrolling level;
3. Listing of timer routine used if not already in benchmark source;
4. Permission to report these data.

I understand that future versions of this Vector Architecture Benchmark may include the names of individuals who fail to meet this agreement, and I would welcome such public exposure should I fail to provide the agreed materials within 30 days.

3480 PERFORMANCE AND CAPACITY PLANNING

Ted C. Keller
Yellow Freight System, Inc.

ABSTRACT

At Yellow Freight our on-line system runs about 23 hours each day. Once a day, we shut our system down, back up our on-line files, and attempt to get back up as quickly as possible. Because of the nature of our system, there is no good time to shut the system down, and we are under constant pressure to keep daily shutdown to an hour or less.

About two years ago, we upgraded from old 3420-type tape drives to the then relatively new 3480 buffered tape units. We expected the anticipated improvements in both performance and reliability to reduce shutdown by 10 to 15 minutes each day.

We were not disappointed by the performance improvements we experienced. Having been quite constrained by our old tape system, we found that not only could jobs run more quickly, but there were also significantly fewer tape errors. After installing the 3480's and then rearranging our schedule to take advantage of the improved performance, we were able to decrease our shutdown period from over 70 minutes to under 50 minutes. Overall, our conversion experience was similar to that described in the Washington Systems Center technical bulletin IBM 3480 Tape Subsystem: Performance Considerations. In the context of our needs, upgrading to 3480's was a positive experience.

As with anything else, the size and scope of our on-line system has continued to expand, and with it, the amount of data to be backed up each day. The duration of our shutdown period began to lengthen, and we suspected that the capacity of the 3480 subsystem might be part of the problem. To help us determine how well our 3480 subsystem was performing, we decided to run a series of benchmarks to provide information about the following important performance issues:

How much work a 3480 subsystem could accomplish;

The impact on through-put of having various numbers of drives active;

The statistical indicators available to measure performance and what they really mean.

In this article I will first briefly describe the functional characteristics of the 3480 tape subsystem, especially those related to performance. Then I will describe how my benchmark was conducted and the results I observed. Finally, I will summarize 3480 performance and performance indicators.

CHARACTERISTICS OF THE 3480 TAPE SUBSYSTEM

The 3480 tape system consists of A22 control units and B22 tape units. The A22 control units are microprocessor driven and each contains 512 kilobytes (Kb) of memory for use in buffering operations. (Newer units come with 1024 Kb, and EC changes are being made available to upgrade older models). Two A22 control units may be connected in a dual configuration mode, and when this is done, each controller can access any tape unit connected to either controller and the buffer storage in each controller.

The microprocessor in the controller manages buffer storage. Memory in the buffer is divided into 8 **buffer segments** of 64 Kb (on older units) or 128 Kb (on newer or upgraded units). One or two buffer segments will be assigned to each active drive. The microprocessor will dynamically assign and reassign buffer segments to different drives depending on activity. When a drive is assigned two buffer segments, they will always be in the same controller and occupy contiguous storage. If most of the activity for a drive is received by one controller, the controllers will attempt to assign the drive's buffer in that controller.

In the normal buffered mode of operation, the channel accesses data only from the controller's buffers. Buffer storage in each controller can be accessed by only one channel at a time. While one controller is transferring data to a channel from buffer storage, no other channel can access buffer storage in that controller.

In a dual configuration, buffer storage will normally be assigned in the controller receiving the first I/O request. This is done to minimize the overhead incurred when one controller needs to access buffer storage in the other controller.

When data is written to the 3480, the controller returns device end and channel end as soon as the data is transferred to the buffer. No further indication is given to the host when the data is finally written to the tape media. (The exception to this is when the unit is operating in Tape-Write-Immediate mode, which is beyond the scope of this paper.) Bufferring allows the application to proceed without waiting for the actual transfer of data to the tape. When data is being read, the unit will read several blocks ahead, pre-staging data in the buffer in anticipation of subsequent read requests from the application.

In the 3480 subsystem, the controller will disconnect from the channel whenever data cannot be transferred to or from the buffer because the assigned buffer is full (write operations) or empty (read operations). The controller will also disconnect from the channel if the buffer being accessed is not available for any of a number of other reasons, such as the buffer storage being accessed by another channel or the buffer being reorganized to adjust the number of buffer segments assigned. The performance measure **disconnect time**, as reported by RMF, is that portion of I/O service time that the channel is disconnected from the controller because the buffer could not be accessed.

On a write operation, several blocks of data in the buffer may be transferred to the tape in a continuous operation. Similarly, on a read operation, multiple blocks can be read into the buffer in a continuous operation. This type of processing, called **streaming**, is considerably more efficient than starting and stopping the tape for each operation. Whenever possible, the controller will attempt to allow devices to process in streaming mode.

The controller, however, will not let one tape drive dominate the subsystem. Since only one drive can access the buffer storage in a controller at a time, the controller may need to stop streaming activity on one drive to allow other drives to access buffer storage. The decision to stop a drive will be made based upon how much data remains to be transferred and the overall amount of activity in the subsystem. When the controller does stop a drive, it times the starting of another drive so that it will be ready to begin transferring data just after the drive being stopped completes its transfer.

Mechanically, 3480 tape drives are slower than the old 3420 type drives. Additionally, since the IBG is so small, the tape will actually move beyond the beginning of the next block whenever the drive stops. To compensate for this, the drive will automatically back up and reposition itself before the IBG each time it stops. This automatic repositioning is called back-hitch. Since the 3480 has relatively slow mechanical start and stop times, it is not as efficient when it must start and stop frequently.

HOW THE BENCHMARK WAS ACCOMPLISHED

We wrote a program which looped writing a specified number of blocks to tape. A crude synchronizing routine was included to allow all tape drives in each test to begin writing at about the same time. Enough data was written to each tape so that it was just over 90 percent full. A blocksize of 16 Kb was used, since that was typical of blocksizes used during our shutdown period. Each tape was written by a separate job, and each job was made non-swappable and given the same dispatching priority. Tests were run using from one to 16 tapes.

The benchmark jobs were run on a pair of 3090 model 200 processors using MVS/XA. One processor was dedicated to the test; the other was processing a minimal CICS workload. Two A22 controllers in a dual configuration were used, each with four attached B22 tape units. Selected drives were varied on-line in different tests to allow selection of controllers. The initial benchmark was run with 512 Kb of buffer storage in each controller. A later benchmark was run after the controllers were upgraded to 1024 Kb, and a summary of the differences is provided in Appendix A.
RMF was used to record various statistical data such as channel and device activity. The reporting interval was set at one minute. When the results were interpreted, only those RMF samples in which all tapes were active for at least 58 seconds of the minute interval were used. (For example, if a particular benchmark run involved using 8 tapes, the only RMF intervals used for most analyses were those minute-long periods in which all eight tapes were active for at least 58 seconds.) This was done to eliminate partial data which could distort statistics.

THE RESULTS OF THE BENCHMARK

The first group of tests to be analyzed used only one tape drive at a time. In these tests, run times varied from 78 - 88 seconds, with a mean of 82 seconds and a median of 80 seconds. (For our purposes, run time includes only the time after file opens and job synchronization that jobs were actually attempting to write to tape.) Separate tests were run on each of the 3090 processors and the results were comparable.

RMF data showed service times for some typical runs (those with run times about 80 seconds) to be 79 - 80 ms. Thus it took about 1000 start subchannel commands to transfer the 10500 blocks, or about 10.5 blocks per start subchannel. Our effective service time was about 7.5 ms per 16 Kb block. During these tests, disconnect time averaged 8.3 - 8.6 ms per I/O or about 0.8 ms per block. This represented about 10.5 percent of service.

The disconnect time probably occurred because the channel was somehow able to transfer data slightly more quickly than it could be transferred to the device. Overall, we were able to transfer about 2.1 - 2.2 megabytes per second out of a theoretical maximum of 3.0. It is probably safe to assume that the device streamed most of the time. In almost every way service was good and, for those used to 3420-class drives, surprisingly fast.

The second group of tests involved the use of two tape drives. Tests were run:

a. on one processor with both tapes on the same controller;
b. on one processor with the tapes on separate controllers;
c. on two processors with the tapes on separate controllers.

The results of these tests were somewhat surprising. To begin with, runs using two tape drives on the same controller followed an unusual pattern. Each run took either 141 - 144 seconds or 114 - 118 seconds, but no run took between 119 and 140 seconds. Similarly, when the tapes drives were on separate controllers, run times clustered in two ranges: from 107 - 113 seconds or from 127 - 136 seconds, with no runs completing between 114 and 126 seconds. When the tape drives on separate controllers were processed from different processors, all runs completed in 94 - 99 seconds.

Exploring the probable reasons for the variations in run times can help provide some interesting insights into the nature of the 3480 subsystem and how it performs.

In the third set of runs using two processors and separate controllers, there should have been very little interference between the drives. Since each of the controllers was defined with a different preferred path, activity should have been funnelled through one controller on each system, and the buffers should have been allocated in separate controllers. There should have been no contention for the channels (different channels on different systems) and no contention for buffer storage. Overall, there should have been very little internal contention and neither tape's performance should have been materially impacted by the other. In theory, we should have expected run times to be just a little longer than in earlier runs when only one tape was active.

Run time did increase by an average of about 12 seconds (or 17 percent) over tests with a single active drive. Average service time was 93 ms per start subchannel command with an effective service time of about 9.0 ms per block. Of this, approximately 2.0 ms (22 percent of service) was disconnect time. If about .8 ms of disconnect time per block could be associated with delays similar to those experienced with a single active drive, the additional 1.2 ms per block of disconnect time would seem to be due to additional controller overhead. This was probably caused by the additional processing and coordination required to keep multiple drives active.

In the first set of the tests with both drives on the same controller, MVS/XA would have attempted to use the same path for both drives (they were defined with the preferred path option to MVS/XA). The path through the second controller would have been used only when the preferred path was busy. This would have caused the buffers for both drives to have been allocated in the same controller most of the time. Since buffer storage in a controller can only be accessed by one channel and by one device at a time, the drives would had to have shared access to buffer storage. Whenever one drive was writing, the other could not; and whenever data was being transferred from a channel for one drive, the other channel was similarly locked out.

It is probably safe to conclude that in those sets of test runs completing in 141 - 144 seconds, the buffers were allocated in the same controller. RMF statistics for these runs show device service time of about 143 ms. Again, it took about 1000 start subchannel commands per tape, with about 10.5 blocks written per start subchannel. The effective service time was about 13.6 ms per block of which 6.6 ms (48 percent of service time) was spent disconnected. About 2.0 ms of the disconnect time was probably caused by overhead similar to that described above. Most of the remainder of the disconnect time (about 4.6 ms per block) was probably caused by contention for buffer storage.

But not all runs using two tape drives on the same controller experienced the same elapsed times; runs in some tests completed in only 114 - 118 seconds. The likely reason for this is that, in these runs, the buffers would have been allocated in separate controllers. If the preferred path was busy doing work for the first tape when the initial write command was issued for the second tape drive, then the alternate path through the second controller would have been used, and the buffers would have been allocated there. With buffers allocated in different controllers, the contention for buffer storage was eliminated. The few times this happened, elapsed times decreased by about 26 - 27 seconds.

In test runs using two tapes on separate controllers, run times were slightly better than when both drives were on the same controller. Run times again clustered in two ranges, 107 - 113 seconds and 127 - 136 seconds. In these tests, since each controller would have been assigned a different preferred path, buffers tended to be allocated in different controllers. Only when one of the preferred paths was busy at the time of the first I/O request would the two buffers have been allocated in the same controller.

We can again see the impact of buffer placement in these test runs, but can also see the impact of two other factors. In these tests, when the buffers were in opposite controllers, most I/O requests were being received by the controller containing the buffer segments. Because of the reduced inter-controller overhead, these test runs completed in an average of 5 - 7 seconds less than the best run times when the two drives were connected to the same controller. Additionally, even when the buffers may have been allocated in the same controller initially, it is likely that the controllers' load-balancing algorithm moved one of the buffers to the other controller. This should happen since the predominance of each tape's work would flow through a different path, and the controllers would attempt to locate buffers where most of the activity was occuring.

Furthermore, with both tapes on the same controller, MVS/XA would have tried to schedule most I/O's for both drives over the same path and should have used one channel more heavily than the other; with tapes on separate control units, activity should have been more evenly balanced between the two channels. In many cases one half of the channel pair was accessed significantly more heavily than the other when both drives were on the same controller, and the channels tended to be more evenly utilized when drives were used from both controllers.

When four or more drives were active, the results were similar to those with two active drives except that run times and device service times became longer as more drives were active, and there were wider variations in run times for reasons explained above. On the average, disconnect time increased to about 63 percent of service time with four drives active, but this varied considerably depending upon several factors. For test runs conducted with additional active drives, service times continued to increase as did disconnect time per block written. With 12 drives active, disconnect time accounted for about 89 percent of service; and with 16 active drives, about 91 percent.

With four active tape drives, chances became good that some buffers would be allocated in each controller. It was unlikely that all four drives

would have their buffers allocated in the same controller. In most cases, each controller would have the buffers for two or three drives, regardless of which drives were used. With five or more active drives, each using two buffer segments (as long as buffer storage would be available in one of the controllers, the controllers would try to allow each active drive to use two buffer segments), some buffers had to be allocated in each of the controllers. With multiple active drives, sometimes the workload appeared to be balanced between the controllers and sometimes it appeared quite unbalanced. It was not uncommon to see one or two tapes finish as much as 100 seconds sooner than the other tapes in the same test when larger numbers of tape drives were used.

With four active drives on one processor, channels were 80 - 90 percent busy during most tests. Additionally, subsystem connect time per second (the time a channel was connected to a controller transferring data) totalled between 100 and 104 seconds per minute. The tape subsystem was being used to about 86 percent of its theoretical capacity.

Overall, subsystem throughput increased as more tapes became active but seemed to peak with six active drives. About the same amount of work could be done per unit of time with anywhere between five and eight active drives. With nine or more active drives, throughput began to fall (both total connect time per minute and channel busy measures decreased.) Less total work per minute took place with 16 active drives than with three.

With nine or more active drives, some drives would have to be assigned less than two buffer segments. Normal controller overhead also continued to increase with more drives. With large numbers of active drives it is also quite likely that buffer segments would be stolen from some drives and reassigned to others that may have appeared more active from time to time.

Five to eight active drives seemed to provide maximum levels of throughput. (In some cases, this same level of work could be accomplished with only four active tapes.) With five active drives on one processor, the sum of channel busy percentages for all active channels was normally over 180 percent. Total connect time was about 110 seconds per minute. Total channel busy and total connect time per minute remained fairly constant with five to eight active drives. But, of course, even though the amount of work accomplished per unit of time remained stable in this range, run times and block service times increased when more drives were active.

CONCLUSIONS AND SUMMARY

The 3480 tape subsystem is powerful but complex. Factors over which we have little or no control, such as the location of buffers, can have a significant impact on performance. It is difficult to obtain completely repeatable results, even in a closely controlled benchmark. Because of this, it is difficult to accurately assess performance experienced in any given situation. Instead, when analyzing the 3480 subsystem, it is important to review the results of several related or similar periods.

The best indicators of total work accomplished (throughput) were total channel busy (of all tape channels in use) and total connect time per minute. With five to eight active drives, total channel busy averaged just over 180 percent, and total connect time ranged from 106 to 110 seconds per minute. With six active drives, total connect time and channel busy normally were just a little higher than with any other number of active drives. Figure 1 shows total channel busy values for different numbers of active drives.

It would seem from total channel busy figures that throughput might have peaked at about 5.5 million characters per second (cps) (3 million cps * 2 controllers * 95%). However, effective throughput (total characters transferred to tape by all runs of a test divided by the mean run time of all jobs in that test - remember that our run times include only transfer times and exclude mount, open, and rewind times) was always considerably less. No run achieved effective throughput better than about 4.6 million cps. For runs with a single active drive, the best effective transfer rate was about 2.2 million cps; total channel busy measured during that run was 90.8 percent, which at a 3 million character transfer rate would seem to have been about 2.7 million characters per second. With two active drives, the best effective transfer rate was 3.6 million cps, while channel busy values suggested higher performance. Throughout all of these tests, effective transfer rate peaked at 2.2 - 2.3 million cps per controller.

Jobs ran faster with fewer active drives. With only one active drive, a tape could be written over 90 percent full in about 80 seconds. With two active drives run times climbed to 94 - 144 seconds, depending on whether one or two processors were used, where the buffers were allocated, and on which paths the drives were located. Run times continued to lengthen with additional active drives, and were as high as 850 - 950 seconds with sixteen active drives. Figure 2 shows run times for different numbers of active drives.

The best indicators of performance appear to be the ratios of connect time or disconnect time to device service time. Connect time represents the portion of service time that the channel was connected to the buffer doing useful work; disconnect time is the portion of service time during which the buffer was not available. Normally, unless a tape is being mounted or rewinding, connect time and disconnect time together will account for 99 percent or more of service time. In general, the higher the connect time ratio or the lower the disconnect time ratio, the better the performance the device is receiving.

Connect time ratios ranged from about 90 percent with a single active drive to about 8 percent with sixteen drives active, while disconnect ratios ranged from about 10 to 91 percent, respectively. Connect ratios of 20 to 35 percent were common during periods of high system throughput (five to eight active drives). Figure 3 shows the correlation between connect time ratios and total run times. Figure 4 shows connect time ratios for minute long intervals, and Figure 4-A shows the mean

connect time ratios for various numbers of active drives.

A number of other tests were run to briefly explore other aspects of performance. In one test, we increased the blocksize to 32 Kb; here run times improved by about 8 percent with a single active drive, and total effective throughput climbed to 2.4 million cps. In some tests we tried smaller blocksizes (2 Kb) and mixing runs using both files with large and small blocksizes. In these tests, we found that not only did it take longer to fill a volume with smaller blocks, but that in the tests using both large and small blocksizes, the smaller blocksizes hindered the writing of larger blocks. In some later runs, we tried reducing the number of host buffers (DCB=BUFNO) from 20 to 8; we found no noticeable difference with one active drive, but detected slight improvements in elapsed time with multiple active drives.

This study and benchmark concentrated on 3480 subsystem performance when writing large amounts of data to tape. All files in my tests were being pushed as hard as possible. My tests purposely excluded mount, open, and rewind times. In most environments, though, we do not usually find such levels of stress by all active drives. Most jobs have other things to do besides write data to tape and will not normally attempt to write data as intensely as our tests did. It is also probable that some number of drives will be loading or rewinding at any given time. These tests were designed to determine the processing limits of the 3480 subsystem when writing large volumes of data, and may not be completely suitable for analysis of tape workloads which include a wide range of various kinds of activity.

While I have discussed the operating characteristics of the 3480 subsystem, described a series of benchmarks, and summarized their results, I have not yet demonstrated how all this information can be useful. In Appendix B, I have included the results of a study I recently completed relating 3480 performance to specific capacity analysis.

APPENDIX A

SUMMARY OF PERFORMANCE DIFFERENCES AFTER THE MEMORY UPGRADE

After memory was upgraded to 1024 Kb on each of our 3480 A22 units, I reran many of the benchmark runs. As might be expected, there was some improvement at all levels of processing.

With a single active tape drive, run times for eight separate runs were all between 75 to 77 seconds. This was not only a little better than all similar previous runs, but more consistent; run times had ranged from 78 to 88 seconds with a mean of 82 seconds. Effective transfer rate now peaked at 2.3 million cps versus 2.2 million cps previously. Total channel busy was about 94% during these runs, compared to a peak of 88% before the upgrade. Connect time was 95 - 96% of service, up from 90% previously. Figure 5 shows run times for different numbers of active drives.

Tests with two active drives followed patterns similar to those in previous benchmarks except that run times were shorter and the impact of buffer placement appeared to be less obvious. With two drives on a single control unit, run times were 100 - 123 seconds with a possible break in ranges around 110 seconds. With the two drives on separate controllers, individual run times ranged from 87 to 122 seconds with no discernable pattern. When the two drives were accessed from separate processors, run times fell to 78 - 107 seconds. Depending upon several factors, run times varied considerably but were consistently better than before the upgrade. Channel busy values were correspondingly higher as was effective transfer rate. With as much variety as there was in each set of run times, it is hard to give meaningful percentages of improvement.

As was the case before the upgrade, total throughput peaked with six active drives (at 4.9 million cps). Throughput was consistently good with up to eight active drives and did not decline materially until more than 12 drives were active. In fact, even with 16 active drives, total channel busy was over 170 percent and the effective transfer rate was over 4.2 million cps.

The ratio of connect or disconnect times to service time continued to be a good indicator of performance. With a single active drive, connect/service ratios averaged 95 - 96%. In periods of high throughput, ratios of 35 - 50% were common. With 16 active drives, 10 - 13% was typical. Figures 6 and 7 show the relationship of connect time ratios to run times and to the number of active drives.

The addition of memory to the 3480 controllers appears to have helped performance, especially when more than eight drives were active. While only improving run times by less than 10 percent with four or less drives active, the additional memory facilitated streaming when larger numbers of drives were active and permitted vastly improved levels of throughput at higher levels of activity. It is easy to see in Figures 2 and 5 the differences in performance after the upgrade.

APPENDIX B

A CASE STUDY IN 3480 PERFORMANCE

Once a day, we shut down our on-line system and create backups of our on-line data. The time that we are down is critical, and we attempt to minimize it as much as possible. At the time of this study, the shutdown period had grown just beyond critical limits, and we were interested in determining whether additional 3480 controllers could be of any benefit. This study was performed after memory in the controllers had been updated. Benchmark data referenced was from runs using the upgraded controllers.

The first step taken was to run Omegamon with DEXAN on several selected runs for several days. This would tell us the major components of the jobs' run times. Unless tape processing delays were a considerable percent of run time, there would be no need to look any further.

DEXAN showed us that at least 25 - 36% of the wait time for these jobs was associated with tape processing. A slightly larger percent was for DASD processing, and about 15 - 20% was caused by other delays. These percentages varied from job to job and from day to day, and at times tape processing accounted for as much as 50% of response time, but was seldom less than 25%. The limit of benefits to be expected from tuning 3480 processing would be about 25 - 36% of processing time.

The next step in my analysis was to review RMF statistics for the 3480 devices and channels. For this special analysis, we shortened RMF's reporting interval to one minute and increased sampling to 10 times per second. The reason a one minute interval was selected was that individual jobs might run for only 10 to fifteen minutes, and most drives would process several different tapes and even different files within a ten to fifteen minute period.

RMF showed that connect time was normally 20 - 30% of service for most drives in use during shutdown. While this varied considerably from minute to minute and day to day, this range of performance tended to be common during a large portion of our shutdown period, and there were many periods of five to ten minutes in which connect time ratios of active drives seldom rose above 20 - 25%.

Using this information and information from Figure 7, I saw that connect-service ratios of 20 - 30% corresponded to a level of work generated by 6.5 to 10 very active drives. If this work could be fairly evenly split with another controller, we should expect the level of activity to drop approximately in half. As shown in Figure 8, this should result in an improvement in the connect-service ratio to about 38 - 50%.

Looking at Figure 9 we can see that the projected improvement in the connect time should result in an improvement in the amount of work we should be able to accomplish. Using the correlation between run times and average connect-service ratios as an approximate indicator, we should reduce tape delays by about 50%. It is somewhat difficult to estimate exactly how much improvement might be expected because of the wide range of performance experienced in controlled benchmark runs.

Since only about 25 to 36% of the total elapsed time was attributable to 3480 processing, we could potentially reduce our processing time on key jobs by 13 to 18 percent. Further examination of our shutdown period showed that only about 40 minutes were truly "tape intensive." From this it appears that shutdown could be reduced by 5 - 7 minutes if two A22 controllers were added.

Similar calculations were performed analyzing the impact of proposed expansion to our on-line system. Additional volumes would need to be backed up each day, and those back-ups could be run either after existing jobs completed (thus directly extending our shutdown period) or at the same time existing jobs were running using the 2 - 3 tapedrives that are free during most of the shutdown period. Using a technique similar to that described above, I figured that running two or three additional tape intensive jobs could extend shutdown by 3 to 10 minutes each day if the additional controllers were not added.

Transaction Resource Demand

James T. Cheeseman
3M

ABSTRACT

Transaction chargeback is a matter of increasing concern. Most current charging schemes fall within two general categories:

- Fixed Transaction Cost
- Variable Transaction Cost Based On Resources Used

Both of these methods have their own set of problems, but neither of the methods provides a real measure of Resource Demand - how difficult will it be to provide resources for this set of transactions such that the required response time performance objective is met?

This paper presents a method which provides a quantitative measure of Resource Demand. It includes known parameters which can directly gauge the level of resources needed to service transactions in an interactive transaction oriented system.

Using the measure described in this paper, transactions can be assigned to groups which have similar Resource Service Demands. Charges can then be assigned to relate transaction cost to the degree of system resource consumption.

If chargeback is not the central issue, this measure can be used to rank transactions into groups which warrant special treatment to minimize particular performance problems.

BACKGROUND

With the initial installation of the Information Management System (IMS[1]) at 3M, a recharge method was implemented to apply a fixed charge per IMS transaction. As the IMS workload continued to increase, and the disparity between transactions increased, it became apparent that the method of charging must change to more accurately reflect the resource demand of each transaction. Resource demand is a good measure because it quantifies the actual demand on system resources necessary to meet established response time performance objectives for the transactions.

Discussed in this paper is a transaction charging technique that determines transaction charges based on the physical resource demand of the transactions. Although this paper is directed towards IMS, this method would apply to any transaction oriented system which has established response time performance objectives.

Charging Algorithms

Most charging algorithms can be reduced to two general methods to accomplish transaction charging:

1. Fixed Charge

   This is probably the simplest method of charging - each scheduling of a transaction costs a fixed amount. This is a good charging method if all transactions are created equal. However, since a transaction costs the same amount regardless of how much work is done, there is a temptation to make each individual transaction do more and more work. This causes a large disparity in transaction resource demand, and does not result in an equitable charging method since the longer running transactions are subsidized by the shorter running transactions. This also leads to scheduling difficulties since a greater number of IMS Message Processing Regions (i.e., Resources) are needed to guarantee meeting response time performance objectives for the longer running transactions.

2. Variable Charge

   This is probably the most equitable method since each scheduling of a transaction is charged based on the number of actual service units (or some other measure) consumed. The problem with this method is that each time a transaction is scheduled, the charge is different based on the actual amount of work done. This method makes it extremely difficult to forecast application system costs. There are also implications involving the cost per transaction computation - as the amount of work done by each transaction varies from month to month, the cost per transaction will also vary based on the budget amount to be recovered.

Transaction Resource Demand

A method has been developed which not only offers a compromise between these two methods, but is superior because it gauges the resource demand of transactions. In other words, how much demand is placed on system resources to service the transactions and guarantee that established Response Time Performance Objectives will be met?

The formula, derived in Appendix A, is:

$$F = \frac{A * R * E}{R - E}$$

Where F = Resource Demand Factor
A = Peak Hour Arrival Rate
R = Response Time Performance Objective
E = Transaction Residency Time

The Resource Demand Factor represents

> "The number (or fraction) of message processing regions required to sustain the given transaction arrival rate and meet the required Response Time Performance Objective"

and is a true measure of transaction resource demand. Appendix E contains an analytic model verification of this formula.

The three parameters in this formula are known values for existing transaction workloads: the Peak Hour Arrival Rate and the Transaction Residency Time can be obtained from standard monitoring software products; the Response Time Performance Objective is obtained from customer service agreements.

The three parameters of this formula are interpreted as follows:

1. Transaction Residency Time, E

   Residency time is the amount of time a transaction is resident in a message processing region.

   Residency time is a good measure since it inherently includes database I/O (the more I/Os done, the longer the residency time), database contention (waiting for I/O), and processor time. Since residency time is measured from the point when a transaction starts execution, scheduling delays are not a part of this time. A Program Reuse option, or the use of a program preload software product such as Quick-Fetch[2] or Virtual Fetch[3], has the effect of reducing average residency time since the average application program load time is reduced or nonexistent.

   It should be noted that residency time is adversely affected by the traversal of a disorganized database - extra processing time is required by the system to locate records in overflow areas. Since an increase in residency time causes an increase in cost, the tendency will be to schedule occasional database reorganizations.

2. Peak Hour Arrival Rate, A

   The Peak Hour Arrival Rate is the maximum arrival rate expected or experienced for this transaction over all hours.

   Peak Hour Arrival Rate was chosen since it provides a measure of the wors case for which resources must be provided. For example, if the Peak Hour Arrival Rate is 1 transaction per second, the resources needed to process a given set of transactions is considerably different than if the Peak Hour Arrival Rate is 10 transactions per second. The Resource Demand Formula shows a factor of 10!

3. Requested Response Time, R

   The Requested Response Time is the response time expected by the user according to an established Response Time Performance Objective.

   The Requested Response Time is necessary since it is the driving force that determines how fast a transaction must be serviced and, consequently, the amount of resources which must be provided. Given any residency time, obviously, more resources are needed to provide service for, say, 5 second response time than would be needed to provide service for 10 second response time.

   Since most response time performance objectives are stated in terms of a statistical confidence level statement such as:

   > "95 Percent of the transactions will complete in less than R seconds",

   an arbitrary choice of the confidence level to use must be made. The choice is arbitrary since the total amount recovered should approximate the cost of providing the service. Appendix D contains a discussion and derivation of a method that can be used to convert from a chosen confidence level to a different confidence level.

This formula has some rather interesting properties and implications. Since the denominator is a difference which can approach zero, the formula is of exponential form. This is seen frequently in queueing systems. The exponential form is expected since as the transaction residency time (E) approaches the response time performance objective (R), the number of message processing regions required (F) must necessarily be large.

An example will demonstrate the nonlinear behavior of this formula:

Given a peak hour arrival rate of 1 transaction per second and a residency time of 0.75 seconds, 3 message processing regions are required to meet a performance objective of 1 second. Whereas, if the residency time is 0.5 seconds, only 1 message processing region is necessary!

This demonstrates that, for these conditions, the first transaction has a residency time 50% greater than the second transaction, but it requires 3 times the resources to be processed!

However, if the Requested Response Time of the first transaction is increased to 3 seconds, then only 1 message processing region would be required.

Appendix B provides a graphical example of the comparison between two transactions that have different resource demand factors.

Boundary Conditions

Since an exponential equation has some unique properties, it is helpful to examine the boundary conditions.

In the case where the transaction residency time is equal to the response time performance objective, the resource demand factor is infinity. This means an open message processing region must be available whenever a transaction arrives in the system - otherwise a delay will occur. Thus, the number of message processing regions established must be equal to the expected maximum number of transactions that could be in the system concurrently. To have less than this number of message processing regions means that a delay will inevitably occur, causing the response time performance objective to not be met. The number of message processing regions could be slightly less if the response time performance objective was stated in terms of a confidence level for the response time performance objective.

In the case of the residency time exceeding the requested response time, the Resource Demand Formula gives a negative value. This indicates that it is impossible to provide a response time that is less than the amount of time a transaction is resident.

Transaction Resource Usage Ranges

Since it probably would not be practical to have a different charge for each unique transaction, a system of categorizing the transactions into resource usage ranges provides a more reasonable alternative. It is relatively easy to obtain average residency times and peak hour arrival rates of existing transactions over a period of time. Using these values, along with established Response Time Performance Objectives, the range of values for the Resource Demand Factor can be computed. Depending on the number of price categories desired, the range of Resource Demand Factors can be divided into Resource Usage Ranges. Given the total amount of money that must be recovered over a given period of time, along with the projected transaction volumes, a price for each category can be assigned. An example of price categories is shown in Appendix C.

It is desirable to have more than a few categories so that the price differential between categories is not excessive. A small number of price categories could have a significant effect on transactions which fall near the price category borderlines.

In the case of new transactions, the residency time can be estimated from data gathered during transaction testing or, perhaps, from a transaction estimation tool. This will allow assigning the transaction into a temporary category while long term averages are obtained.

It is suggested that long term tracking of peak hour arrival rates and residency times be done for each transaction. This will allow moving transactions between categories if the resource demand changes significantly.

Benefits Of Resource Demand Charging

Since shorter residency time transactions, for a specified response time performance objective, correspond to a lower charging rate, a tendency will be to create small, single purpose transactions to take advantage of the lower cost. From a performance standpoint, this is exactly what is desired since many short transactions place less of a demand on system resources and reduce the scheduling problems inherent in large resource demand transactions. The net effect of this is to consistently meet established performance objectives while postponing costly resource upgrades.

In a recent journal[4], it was stated that in published lists of reasons for chargeback, the item "Promote Optimal Use Of Resources" is never included. Transaction charging by resource demand does this very thing!

An example will demonstrate how Optimal Use Of Resources is promoted by the nonlinear behavior of the Resource Demand Formula. The costs used in this example are from Appendix C and the transaction types are those stated in Appendix B.

Suppose there were 100 Type B transactions which have an associated cost of $0.025/transaction. If these were converted into Type A transactions, to do the same amount of work, 250 transactions would be required. Since the cost for A type transactions is $0.005, the total cost for 250 would be $1.25 - the total cost for the B type transactions is $2.50. Consequently, the cost is 50% for doing an equivalent amount of work.

Conclusion

A method for IMS Transaction charging with a firm base in operational analysis has been developed. This method provides a transaction charging method based on a measure of resource demand which is a function of peak hour arrival rate, IMS message region residency time, and the response time performance objective. The method closely approximates the results obtained in queueing systems.

Acknowledgement

This paper is a result of discussions with T. M. Kabrick of 3M on his idea to develop a method for charging transactions based on the demand placed on system resources to meet established response time performance objectives.

I would like to thank the following people from 3M for their helpful comments and criticisms: T. W. Akemann, J. E. Knutson, M. D. Korich, E. C. Robinson, and J. M. Strom.

A special thanks to Mary Shafer for her effort in transcribing this paper to "CMG Conference Format".

APPENDIX A.

RESOURCE DEMAND FORMULA DERIVATION

This appendix provides the derivation of the Resource Demand Formula using established laws of operational analysis[5].

The response time a typical transaction will experience is:

$$R = N*E + E \qquad (1)$$

Where R = Transaction Response Time
N = The Average Number Of Transactions In The Queue
E = Transaction Residency Time

In essence, this states that the response time a particular transaction will experience will be the residency time for all transactions in the queue ahead of it plus its own residency time.

Little's Law from Queueing Theory states that the number of transactions in the queue is the product of the response time and the throughput.

$$N = R * X \qquad (2)$$

Where N = The Average Number Of Transactions In The Queue
R = Transaction Response Time
X = Throughput (Arrival Rate)

Solving equation 1 for N and equating to N in Little's Law (Equation 2) produces:

$$\frac{R - E}{E} = R * X \qquad (3)$$

Solving for X gives:

$$X = \frac{R - E}{R * E} \qquad (4)$$

If R is interpreted as the requested Response Performance Objective, then X is the maximum throughput that can be processed in a message processing region. Given a peak hour arrival rate A that must be processed, then the required degree of multiprocessing (number of message processing regions) or fraction thereof needed to process the transactions is:

$$F = \frac{A}{X} = \frac{A * R * E}{R - E}$$

APPENDIX B.

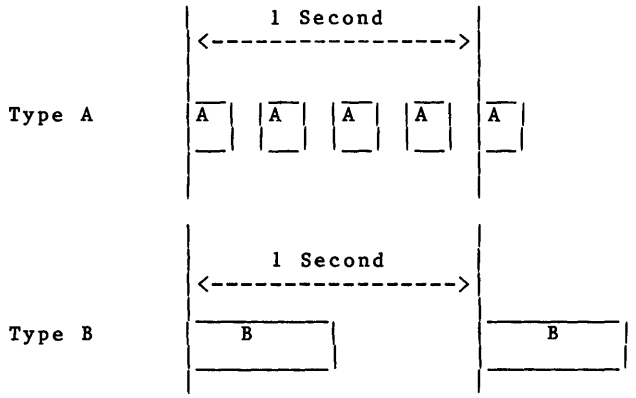
GRAPHICAL EXAMPLE OF RESOURCE DEMAND FACTOR

This appendix contains an example of the effect of transactions with different Resource Demand Factor values.

In this example, two types of transactions were chosen:

Type A	Type B
A = 1.0	A = 1.0
R = 1.0	R = 1.0
E = 0.20	E = 0.50
F = 0.25	F = 1.00

To meet the given response time performance objective of 1 second response time, the Type A transactions require one fourth of a Message Processing Region - or stated another way, four transactions of this type can be processed in one Message Processing Region in one second. The Type B transactions, however, require the full services of one Message Processing Region to meet the given 1 second response time performance objective. This criteria is represented graphically below:



Note that the Type B transactions have 2-1/2 times the residency time as the Type A transactions, but the resource demand to provide the same response time performance objective is a factor of four.

APPENDIX C.

TRANSACTION RESOURCE DEMAND COSTS

This appendix provides an example of transaction cost for the range of resource demand values.

Resource Demand	Transaction Cost
0.00-0.24	$0.005
0.24-0.41	0.015
0.41-1.00	0.025
1.00-1.50	0.050
1.50-2.00	0.070
2.00-2.50	0.090
2.50---->	0.140

APPENDIX D.

CONFIDENCE LEVEL CONVERSIONS

This appendix provides a derivation to quantify a change in confidence level for a response time performance objective.

Assume that the confidence level of the Response Time Performance Objective R in the Resource Demand Formula was chosen to be 95%. That is, 95% of the responses will be less than R seconds. If a request is made to reduce the confidence level to 90% for a given set of transactions, this could be considered equivalent to allowing the residency time of these transactions to increase by some specified amount. If this amount is quantified and used to inflate the value of R in the resource demand formula, then a relationship can be developed to convert between confidence levels.

Since the region of interest is only on values to one side of the mean residency time, the statistical confidence coefficients used are for one-sided tests. The parameter S represents the standard deviation of the residency time.

95% of the responses will be less than:

$$R = E + 1.65S$$

and 90% of the responses will be less than:

$$R = E + 1.28S$$

If we consider that the residency time is expanded, the two formulas can be combined as follows:

$$R = E + 1.65S \quad (1)$$
$$R = E' + 1.28S \quad (2)$$

$$E' - E = 1.65S - 1.28S = 0.37S \quad (3)$$

This relation quantifies the difference in residency time between the two confidence levels. This also is the same amount to inflate R to effectively moderate the response time constraint.

Using this, then, to expand R yields

$$R90 = R95 + (E' - E) = R95 + 0.37S \quad (4)$$

But, from equation (1),

$$S = \frac{R95 - E}{1.65} \quad (5)$$

Substituting this into equation (4) yields,

$$R90 = R95 + 0.37 * \frac{R95 - E}{1.65} \quad (6)$$

Rearrangement gives the result

$$R90 = \frac{2.02*R95 - 0.37E}{1.65} \quad (7)$$

which quantifies the increase for R in the Transaction Resource Demand Formula.

As an example, suppose the residency time E is 0.5 seconds and the 95% response time performance objective is 1 second. The effective 90% confidence level value for R is:

$$R90 = \frac{2.02(1) - 0.37(0.5)}{1.65} = 1.11$$

A comparison of the resource demand factor is:

$$F95 = \frac{(1)*(1)*(0.5)}{1.0 - 0.5} = 1.00$$

$$F90 = \frac{(1)*(1.11)*(0.5)}{1.11 - 0.5} = 0.91$$

This same technique would apply for conversion between any given confidence levels merely by changing the confidence coefficients in equations (1) and (2).

APPENDIX E.

VALIDATION OF THE RESOURCE DEMAND FORMULA

This paper would not be complete without verification that the derived formula conforms to what is expected in a computer system. Analytic models have proved their validity through the years, so a comparison of the Transaction Resource Demand Formula to an analytic model was done. The line for the analytic model was obtained by generating an IMS model and manipulating the CPU service time and the multiprogramming level to obtain 2 second response time for the desired range of residency times.

As shown by following chart, there is a remarkable comparison of the Resource Demand Factor to actual modeling predictions. The curves start to differ near the "knee" of the curve. This coincides with conditions where operation is on the brink of disaster, where a small change in residency time produces a dramatic change in response time. This is an area of operation which would normally be avoided!

One would not expect exact comparison, since a relatively simple formula could not encompass all of the complexities of an analytic model. However, over the interval where most systems operate, there is a very high degree of conformity.

Workload Characterization Using UNIX System Accounting

J. Jerik Tornheim
Richard T. Williams
University of Massachusetts / Boston
BGS Systems, Inc.

ABSTRACT

A UNIX* process is, roughly speaking, a command issued by a user. Berkeley UNIX cuts an accounting record that reports resources consumed by each process. The Berkeley UNIX system accounting utility **sa** reads the accounting records, accregating on either a per user or per command basis. But **sa** output is too fine grained (even after aggregation and sorting) to provide useful numbers for capacity planning. To plan effectively, processes should be combined into workloads, so that cumulative resource use can be analyzed and performance measurements calculated.

We have built **sage** (**sa**, greatly **e**nhanced) to provide an easy method for grouping processes into workloads. **sage** reads a workload specification file provided by the user, to put commands into command-groups and users into user-groups. The user-group and command-group are concatenated to form workload names. Then the existing **sa** routines aggregate useage data for workloads, and sort and display the data. The information that **sage** produces is not available from any other Berkeley UNIX measurement or accounting utility. Preliminary capacity planning decisions can be made using just **sage** outputs and a calculator.

1. sa (Berkeley UNIX System Accounting)

To do any elementary Capacity Planning, you need measurement or accounting data about consumers of service. When UNIX accounting is turned on, an accounting record is cut for each process when it has finished executing [1]. The accounting record consists of fields containing:

- the command name
- the userid
- the groupid
- user-time (time the CPU spent operating in user mode)
- system-time (time the CPU spent operating in kernel mode)
- the beginning time (in seconds since midnight, January 1,1970)
- the elapsed time in seconds
- the CPU storage integral
- the number of I/O operations

Because accounting records are cut only when accounting is turned on, you can report system usage for particular time periods (for example, peak hours) only by turning accounitng on and off, or by filtering the accounting records.

The Berkeley UNIX system accounting utility, **sa**, is the only utility that aggregates these accounting records [2]. **sa** provides many different options for sorting and printing, but because it aggregates based only on userids or on command names, it buries you in numbers. The typical **sa** output contains the option-specified usage figures for each userid or each command, with as many lines in the report as there are userids or commands. Because there may be many hundreds of userids or command names, it becomes very tedious to get useful capacity planning information from **sa**.

sa also provides a 'u' option that reports on each individual process. This report could easily span thousands of lines. When it comes to seeing usage reporting on userids and command names, **sa** ouput is either mutually exclusive or all-inclusive.

2. PROCESSES AS TRANSACTIONS

In capacity planning, the base unit for quantifying workloads is a transaction. There are several inherent shortcomings in using UNIX processes as transactions, or base units of measurement. The first follows from the fact that much work in UNIX is done by forked processes. Resources consumed by forked processes should be charged to the original user-initiated process, but that information is not available in the accounting record. For example consider a simple **make** to compile and link two files together to a single executable

* Trademark of A T & T Bell Laboratories

program. The **make** accounting record may indicate something on the order of 0.05 CPU seconds and 60 elapsed (real time) seconds. But the account records for the two compilations show that each used 5 CPU seconds and 30 elapsed seconds. There is no way to know that the two compiles were forked from the single **make**. Any predictions on future resource consumption based on increased number of **make**s would be significantly underestimated unless the number of compilations was somehow increased, too. A possible solution is to rewrite the Berkeley UNIX accounting utility to include an additional command name field to contain the original user-initiated command.

The second shortcoming involves measuring a baseline response time. The calculated response time for the above **make** might be reasonably close, even though most of the work contributing to the response time is not charged to the **make**. On the other hand, edit commands do get all the work charged to that command. But editing response time should indicate how long it takes the screen to refresh following an editing operation. Because there is a single accounting record for the entire editing session, there is presently no way to determine that value. If an editor were instrumented so that it cut an accounting record for each editing operation, effective response time for editing sessions could be calculated. (Perhaps programmers who design editors should keep capacity planning in mind when they implement their product. You don't need response times to track resource consumption, but you do need them if you do analytic modeling and want to validate the baseline (measured) system.) Given the present limitations in Berkeley UNIX accounting records, elapsed time can be taken as a fair measure of response time for processes that do not fork and do not wait for user input (such as simple compiles and queries like **ps**).

One of our design decisions was to go as far as we could with existing Berkeley UNIX accounting information. We did not want to generate our own, or access or modify the kernel data structures. Inasmuch as no other accounting information is available from Berkeley UNIX that indicates consumers of service, there are no reliable alternatives to using processes as workload building blocks without changing one of our basic design decisions.

Because we have chosen to use processes, we need to consider useful strategies for aggregating processes into workloads. They can be grouped into user-based workloads, command-based workloads, or a combination of the two. Our examples are appropriate for a university environment, where the program was developed. So, three user-based workloads could possibly consist of faculty, student, and system userids. Or you may separate several users who include extensive graphics as part of their workload. The possibilities are numerous.

The choices for grouping commands are equally numerous. You may specify an editing workload or a compiling workload. You may group all the mail routines, or the shell routines, or all the file management routines.

The most informative method for grouping processes is using a combination of user-groups and command-groups. This way you could report of editing done by faculty, or compiling done by students. The best way to visualize this is as a two-dimensional matrix with columns indexed by command-groups and rows by user-groups:

	editing	compiling	mail	misc
students				
faculty				
system				

As you can see, the number of user-groups and command-groups determines how course or fine the resulting performance figures are. Given this functionality, answers to the following questions will be readily available:

1) How much are the courtesy accounts costing?

2) Who are the big **troff** users?

3) What impact on system resources will result from another CS 342 class.

4) What happens if the CS 650 class switches from a compiled language to an interpretive one?

These are hard questions to answer with **sa**. If asked these questions now, the capacity planner or hardware manager must just guess and hope that the guess will not come back to haunt him or her later.

3. sage (OR sa, GREATLY ENHANCED)

sage enhances **sa** by allowing the user the flexibility described above to direct the aggregation of processes.

sage reads a workload specification file, which includes

both a time interval, and description of the aggregated workloads. The interval specification essentially provides the filtering of accounting records mentioned earlier. We felt that while we were aggregating, we could also check for a specific interval. The aggregation description is actually three sequences of regular expressions, with most of the regular expressions followed by a group name.

The first sequence governs the aggregation of commands into command-groups. A command sequence might be:

```
# put "vi", "ed", and "emacs"
# into an "edit" command -group
/^vi$/              edit
/^ed$/              edit
/^emacs$/           edit
# any command beginning with "cc"
# goes in a "comp" command-group
/^cc/               comp
# any command containing "mail"
# goes in a "mail" command-group
/mail/              mail
# any command not already in a
# command-group goes in "-misc"
/./                 -misc
```

As each accounting record is read, the command name is compared to the first regular expression in the command sequence. If a match is found, that command is put into the command-group whose name appears following the regular expression. If no match is found, the second regular expression is compared, and so on. Group names are maintained by a hash table, which is updated each time a match is found.

In the above example, the last regular expression matches any string. This means that any command not already explicitly grouped is aggregated into this "-misc" command-group. We recommend this practice; if you don't do this, you may find your **sage** output longer than the **sa** output you were trying to condense. This is because you generate a unique command-group for each command not matched by this scan of the command sequence, and therefore a unique workload for each user-group that executes that command.

Thus, briefly, to process an accounting record cut by a **sendmail** command, **sendmail** is first compared with **vi**; there is no match. Then **sendmail** is compared with **ed**; again no match. The match occurs when **sendmail** is compared with /mail/, so **sendmail** is put into the command-group "mail." This command-group name is put into the hash table, using the key "sendmail."

The second sequence determines how users are aggregated into user-groups, using a variation on the above method. An example of a user sequence is:

```
# put operator into a user-group
# called "oper-"
/^operator$/        oper-
# aggregates all users containing
# "uu" in a "uucp" user-group
/^uu/               uucp
# aggregates directories
# containing of only numbers into
# a user-group with "CS" as a
# prefix, followed by that
# directory name
/^[0-9]*$/          CS&
```

The hash table for the user-groups is set up first (rather than on the fly, as with command-groups) by processing the password file as follows:

1) The login name is matched against the user sequence of regular expressions. If a match is found, that user is included in the named user-group.

2) If no match is found at the login name level, the path is traversed upward toward the root. Each directory is now matched against the same sequence. Once again, if a match is found, the user is included in the named user-group. If the sequence is exhausted before a match is made, the path is continued upward and a new search for matches begins.

3) If the user's path is traversed all the way to the root directory with no match found, then the user is included in the default user-group. This default user-group is usually the parent directory. For example, if my path is:

/u/umb/cs/crtsy/jerik

then my default user-group is "crtsy."

4) The third sequence of regular expressions is used to negate default user-groups. An example of this third sequence is:

```
# any directory beginning with
# "spr8", "sum8", or "fal8" is
# not a default user-group
/^spr8/
/^fal8/
/^sum8/
```

Suppose Dick's path is:

/u/umb/cs/678/spr87/rtw

indicating that he is enrolled in class CS678 in the spring of 1987. His user-group should probably be based "678" and not "spr87." If a particular directory is matched with any of the regular expressions in this third

sequence, then that directory is not the default user-group.

5) The key to the hash table is not the user name but the userid, since that's what the accounting record contains.

Once again, using the sample workload specification file, "rtw" does not match any of the expressions. Now "spr87" is checked against them all, also with no match. Because this is the parent directory, we check whether to eliminate this as a default user-group. The first expression in the third sequence matches, so at this point there is no default user-group. Now "678" is compared with the second sequence, and a match is found with "/^[0-9]*$/" with the result that he is assigned into the "CS678" user-group. Because a match was found with the second sequence, no default user-group is used, although in this case, "678" is his default user-group (because "spr87" is not).

In addition, our example demonstrates how command and user group specifications use the ampersand character ('&'): if the corresponding group name contains an ampersand, the ampersand is replaced by the string just matched (either the command name or the user/directory name, depending on the context).

Most user paths are designed so that you would naturally want to aggregate users based on common ancestors. Consequently, user names are often not included in the workload specification file, since ancestor names are sufficient for effective aggregation.

When an accounting record is read, the process' user-group name and command-group name determined as above are concatenated and truncated to ten characters to form the workload name. The resource usage figures of the process are aggregated under this workload name. Then with only small changes, we let **sa** sort and print the output into manageable and useful workloads that have been specified by the user.

The 'g' option of **sage** reads in this workload specification file and produces a list of all the user-groups with all the login names in each group. A list of all the command-groups containing specified command names is also produced. By modifying the workload specification file, and then running **sage -g**, the capacity planner can determine how the users and the specified commands are grouped before processing the accounting records.

The 'w' option provides the same output, but first processes all the accounting records. This way, all the processed commands will be listed with the appropriate command group.

4. sage OUTPUT

We have included examples of **sa** and **sage** output to demonstrate the benefits of using **sage**. Appendix A is the output from **sa -m**, based on login names. Appendix B is the output from **sa**, based on commands. Appendix C is the output from **sage**, based on workloads. We did not change **sa**'s internal structures, sorting routines, and numerical aggregation, and made only minor changes in the output options. We have designed **sage** so as to change normal **sa** output routines as little as possible. Because **sa** outputs are usually very long, column headers are not good field labels. In **sa** output each variable has a suffix which defines its value. For example the "l" option produces lines with the format:

```
17146.06re    37.06u    37.06s    27avio    74k
```

(In this example, we do not show the first and last columns, which are the number of individual processes and the command name.) The suffixes for the shown (middle) five columns are (in order):

1) real (or elapsed) time
2) user time
3) system time
4) average number of I/O operations per process
5) cpu-time average core usage

These suffixes make a busy report. For short reports headers would be better. So we have added an "h" option, which only displays the suffixes on the first line and suppresses them on the rest.

sa does not provide the beginning time of a process. We discussed response time and forking questions above. We see no resolution, so we provide an 'e' option, which displays the complete contents of the accounting record, including the start time. With this information, it may be easier to track forked processes. The 'e' option disables all aggregation.

A possible future post-processor might produce the two-dimensional matrix shown earlier with appropriate values in each box, or input to a spreadsheet, database, or graphics package.

5. SUMMARY

To do elementary capacity planning, it is necessary to quantify the types of work done on a system. If arrival rates and service time at the CPU and disks can be measured or calculated, then it is possible to derive utilizations, response times, queue length, and other values necessary for capacity management. Berkeley UNIX presently lacks a utility or method to specify types of processing. In order to obtain resource consumption figures for that processing, **sage** provides this functionality. Consequently, for small systems, **sage** output and a calculator is sufficient to do elementary capacity planning.

For systems with an extended configuration or critical performance criteria, a more sophisticated method of analysis is needed. Capacity planners can construct an analytical model of their system which can then be evaluated using a queueing theory software package.

sage is presently being used at the University of Massachusetts. Several professors who do consulting work at other companies intend to use **sage** at these other sites. **sage** source code will be available to interested users.

We have included the proposed UNIX Programmer's Manual page for **sage** as Appendix D.

ACKNOWLEDGEMENTS

We would like to express our appreciation for the feedback from members of the Computer Science Department of UMass/Boston. In particular, we are indebted to Professor Ethan Bolker. Without his help, guidance, and good humor, this project (and paper) would not have been possible.

APPENDIX D

SAGE(8) UNIX Programmmer's Manual SAGE(8)

NAME

sage - system accounting (sa, greatly enhanced)

SYNOPSIS

/etc/sage [-abcdDefghjkKlmnrtuvw]
[-G groupfile] [-P passwdfile]
[-S wklsummaryfile] [-W wklspecfile]
[rawacctfile]

DESCRIPTION

sage condenses accounting information by user-specified workloads and gives aggregate reports on the workloads, a la sa(8), over a specified time interval.

If a file name is given as the last argument, that file will be treated as the accounting file; /usr/adm/acct is the default.

sage takes input of two types. One is system accounting data, as accumulated by accton, in the file /usr/adm/acct. The other is workload grouping descriptions, specified in the file /usr/adm/wklspec. This file consists of four parts. The first part contains information about the time interval you are studying. The second part contains a sequence of regular expressions which are used to group commands into command-groups. The third part contains a sequence of regular expressions used to group login names into user-groups. The fourth part contains a sequence of regular expressions which are used to eliminate particular default user-groups. The division between the first and subsequent parts of the wklspec file are lines which start with an equal sign ('='). Blank lines and lines beginning with a number sign ('#') are ignored.

The first part of the wklspec file contains the starting time of the interval that you will be studying, in 24 hour format, and the length of the interval, in minutes. For example: 10:00 30 indicates an interval of thirty minutes, starting at 10:00 am. 15:15 45 indicates an interval of 45 minutes, starting at 3:15 pm. It is assumed (rather pretentiously) that accounting data for one day only is stored in the input file /adm/acct. To insure that, accton should be run from a shell script that restricts its duration.

Each regular expression in the second and the third part is followed by a group name. As each accounting record is processed, the command name is compared to each regular expression in the second sequence until a match is found. If a match is found, that command name is put into the command-group whose name appears following the regular expression. An example of a command sequence is:

```
# put vi, emacs, and ed into
# an "edit" workload
/^vi$/      edit
/^emacs$/   edit
/^ed$/      edit
# put all commands containing "mail"
# into a "mail" workload
/mail/      mail
# put everything else
# into a "-misc" workload
/./         -misc
```

Before processing any accounting records, all login names in /etc/passwd are put into user-groups. Each login name is compared to each regular expression in the third sequence until a match is found. If a match is found, the corresponding userid is put into the user-group whose name appears following the regular expression. If no match is found, the path is traversed up to the root, with each directory compared against the same sequence. An example of a user sequence is:

```
# put "operator" into an "oper-"  workload
/^operator$/   oper-
# put all directories with only numbers into
# a workload beginning with "CS"
/^[0-9]$/      CS&
```

If there is no match found with the third sequence, a default user-group is used. This is the lowest directory name which does not match any regular expression in the fourth sequence. An example of a default sequence is:

```
# any directory beginning with "spr8" is not
# a default user-group
/^spr8/
# "crtsy" is not a default user-group
/^crtsy$/
```

sage output fields are those of sa, except the obvious: sage prints workload names where sa printed commands or login names. Some fields are labeled:

"cpu"	for the sum of user and system time (in minutes),
"re"	for real time (also in minutes),
"k"	for cpu-time averaged core usage (in 1k units),
"avio"	for average number of i/o operations per execution.

With options, fields labeled:

"tio"	for total i/o operations
"k*sec"	for cpu storage integral (kilo-core seconds),
"u"	for user cpu-time alone (in minutes),
"s"	for system cpu-time alone (in minutes).

sage retains most of sa's googol of options, and adds a few dozen more:

a Print all workload names, even those containing unprintable characters and those used only once. By default, those are placed under the name '***other'.

b Sort output by sum of user and system time divided by number of calls. Default sort is by sum of user and system time.

c Besides total user, system, and real time for each workload, print percentage of total time over all workloads.

d Sort by average number of i/o operations.

D Print and sort by total number of disk i/o operations.

e Superseding all other flags, print the entire contents of each accounting record, preceded by the appropriate workload name and login name. Aggregation is disabled.

f Force no interactive threshold compression with -v flag.

g Without processing the account records, read the wklspec file and print out the login names for each user-group and the specified commands for each command-group.

h Suppress the suffix description for each value except on the first line (the "h" stands for "header").

j Instead of total minutes for each workload, give seconds per call.

k Sort by cpu-time average memory usage.

K Print and sort by cpu-storage integral.

l Separate system and user time; normally they are combined.

m Print number of processes and number of CPU minutes for each workload.

n Sort by number of calls

r Reverse order of sort

t For each workload report ratio of real time to the sum of user and system times.

u Superceding all other flags (except the "e" flag), print for each process in the accounting file the userid, cpu seconds, cpu storage integral, i/o operations, and command name.

v Followed by a number n, types the name of each workload referenced n times or fewer. Await a reply from the terminal; if it begins with 'y', add the workload to the category 'junk'. This is used to strip out garbage.

w After processing the account records, print out the login names for each user-group and the commands for each command-group.

G The following filename is used as the user-group and command-group listing file instead of /usr/adm/wklgroup.

P The following filename is used instead of /etc/passwd as the system password file.

S The following filename is used instead of /usr/adm/wklacct as the workload summary file.

W The following filename is used instead of /usr/adm/wklspec as the workload specification file.

FILES

/usr/adm/acct	raw accounting
/usr/adm/wklgroup	user-group and command-group listing
/usr/adm/wklspec	workload specification
/usr/adm/wklacct	per-workload summary
/etc/passwd	system password file

BUGS

The number of options to the program is absurd.

A BENCHMARK COMPARISON OF DB2 AND THE DBC/1012

G.C. Steindel and H.G. Madison
Great-West Life Assurance Company

ABSTRACT

Over time Information Services departments have attempted, in a timely manner, to provide adaptable, maintainable, and cost effective applications to support the information requirements of their organizations . From this need and desire have evolved the use of shared data-base management systems(DBMSs) and the techniques of data modeling and normalization. While providing adequate performance, DBMS's based on the hierarchical and network models have failed to achieve acceptable levels of application adaptability, maintainability, and ease of use. The relatively recent introduction of DBMS's based on the relational model and the use of entity-relationship data modeling techniques however, appear to hold promise for addressing these shortcomings, though at a possible detriment to performance.

The results oriented nature of relational data-bases(RDBs) which require the specification of the desired results rather than the method for attaining the results has facilitated the implementation of these systems in specialized hardware in addition to the more traditional software approach. The relational data-base machine approach has the potential to offer improved price-performance over software implementations on general purpose hardware and is of extreme interest considering the general concern over responsiveness of relational systems.

This paper presents an initial comparison of these two approaches to providing relational services by contrasting the cost and performance of IBM's DB2 and Teradata Corporation's DBC/1012 through the use of a benchmark.

1.0 INTRODUCTION.

Great-West Life is a large Canadian insurance company utilizing primarily IBM hardware and software. Most applications have been developed in-house using IMS technology. Although this technology for the most part has allowed the company to accomplish its objectives it has been highly labour intensive in data-base design, as well as application maintenance. While providing the necessary basis for the day to day administrative tasks of the company these applications have not effectively addressed the need for the accessibility of management information that was assumed to be available with data-base technology.

The advent of relational data-base technology appeared to address many of the problems which Information Systems departments had been having with IBM's hierarchical data-base approach. Data-base design efforts would be greatly reduced by allowing normalized entity-relationship data models to be mapped directly into relational tables. Adaptability of both applications and data models would be enhanced by the ability to readily add new tables and entities without disrupting existing applications through the use of techniques such as views. Accessibility of data would be improved by providing the more business intuitive paradigm of the table, and removing the responsibility for data-base navigation from non-technical people attempting to find information. These benefits although laudable and necessary in the business community would likely not come free. Rumors still run rampant today about the ability of relational data-base systems to consume general-purpose processors with the greatest of ease. Since relational systems are based on the principle of describing the results required rather than the method necessary to attain the results, they by nature have a straightforward and highly structured language as their interface. This has opened the possibility of developing special purpose hardware for the delivery of relational services. The incentive for these sorts of developments are oriented primarily to providing higher levels of performance and reduced cost relative to conventional software based systems.

Over the last year Great-West Life, like many other IBM installations, installed IBM's Data Base 2 (DB2) [1] relational product and experimented with it in a variety of test applications which were primarily of a decision support nature. During this investigation period we encountered several situations where staff were readily able to formulate queries which would consume what the data centre staff felt were inordinate amounts of processor resources. These situations heightened our awareness of the potential performance problems that relational processing might bring if adopted in a full scale production environment , and subsequently prompted us to investigate other means of providing relational services. In mid 1986 we became aware of a relational data-base machine product offered by Teradata Corporation of Los Angeles, California which appeared to fit reasonably well into our IBM mainframe environment. In order to evaluate the Teradata product known as the DBC/1012 [2] we decided to conduct a benchmark comparison between it and DB2. The remainder of this paper will discuss the objectives, environment, results and conclusion of the benchmark.

2.0 BENCHMARK OBJECTIVES.

While still being fairly new at the DB2 game the first objective of the benchmark was to determine just how far we could push our 3090-200 system with query workloads. We had seen several instances where complex queries had used large amounts of processor resources but were not sure just how many of these it would take to saturate our system. We anticipated that this was an item of concern since the accessibility which the relational approach afforded the owner of a database would increase the demand for large database inventories and management reporting. This type of workload would be primarily of a batch nature in the off shift. However, if our interactive query experience was any indicator, it would be considerably more processor intensive than had been our previous experience with other non-relational over night batch processing. The primary orientation of this part of the benchmark was toward throughput, and capacity of a system.

The second objective of the benchmark was to compare the performance of an interactive query workload. Here the factors of interest were primarily elapsed time and processor resources consumed which is the primary element of cost to the requestor.

While up to this point Great-West Life's usage of relational processing was focused on query type applications aimed at providing improved management reporting, we realized that our benchmarking activities would have to cover the area of transaction processing in order to provide a relatively complete picture of the products' capabilities. It was anticipated that over time the existing IMS applications would begin to include relational components as they were maintained or redeveloped. Again, the measures of responsiveness and resource consumption were of prime interest. While the issue of throughput was quite important to us in investigating transaction oriented systems we were unable to delve into it due to the significant effort that would have been necessary to build transaction drivers that were portable to the Teradata benchmark facilities.

Lastly, any additional information that could be gleaned about utility, data-base load processing, and index creation performance would be considered gravy.

3.0 TERADATA DBC/1012 SYSTEM OVERVIEW.

The DBC/1012 is a special purpose computer specifically designed to execute SQL relational data-base queries and updates generated from a general purpose computer. The general purpose host runs a special application called the Teradata Director Program (TDP) [3] which is used to interface between the DBC/1012 and the host applications requesting relational services. The TDP receives SQL requests from the various application programs running in either a MVS or VM host. These requests are then transmitted to the DBC/1012 across a standard 370 block multiplexer channel . Each channel is connected to an Interface Processor (IFP) on the data-base machine as is shown in Figure 1. The IFP is responsible for parsing the SQL request and developing the execution plan which it then schedules on the Access Module Processors (AMP's). Attached to each AMP are one or two Disk Storage Units (DSU's) on which the tables are stored. All AMP's and IFP's are connected together with a branching tree-like device called the Y-net shown in Figure 2. The Y-net is the part of the DBC/1012 which facilitates the broadcasting of requests to, and merging of results from the AMP's which operate in parallel to produce a relational result. When the AMP's have completed the execution of an SQL statement the results are transmitted to the IFP which send them back up the 370 channel to the TDP and subsequently to the appropriate host application.

AMP's using a hashing technique. If an IFP determines that a row of a table can be accessed by its primary key, the key is hashed to determine the appropriate AMP and followed by a single AMP disk search to locate the row. The result row is then returned up the Y-net to the IFP. If an IFP determines that the result rows reside on more than one AMP the request is sent up the Y-net toward the root, turned around, and broadcast simultaneously to all AMP's. Each AMP then performs the appropriate disk search and simultaneously present their results to the Y-net. The Y-net then performs a balanced-line merge, continually selecting the result row with the lowest key value from the AMP's until all result rows are transmitted to the IFP.

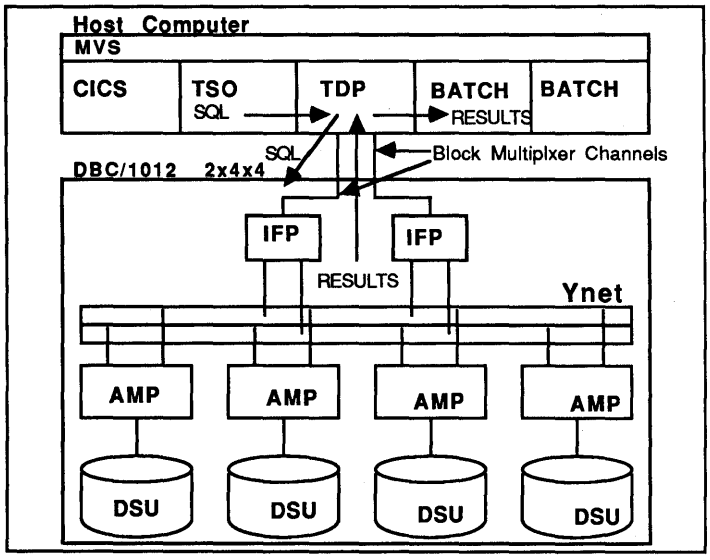

Figure 1. MVS Host - DBC/1012 Configuration

For each non-unique secondary index (or non-unique primary index) defined on a base table, an additional table is stored on each AMP [4]. These secondary index tables contain the secondary key values for the base rows on their own AMP. The secondary index also contains one or more track addresses of the appropriate blocks containing base rows of each non-unique key. Unique secondary indices are treated as a special case of uniquely keyed base tables and are accessed by hashing the secondary key valued to select an AMP which then determines the corresponding primary key value which is hashed to determine the AMP containing the base table row.

The larger the number of AMP's attached to a DBC the more parallelism that is incorporated into table searches, and the faster the response to a data-base request. Teradata has benchmarks which show that query response times decrease linearly with the increase in the number of AMP's within a tolerance of approximately 4% error.

The Teradata Query Language (TEQUEL) which is used to manipulate data on the DBC/1012 is very similar to IBM's Structured Query Language (SQL). In addition to being able to code TEQUEL in various third level language programs, which is translated by a language preprocessor, host utilities are provided for the direct submission of TEQUEL to the DBC/1012 via the TDP.

4.0 BENCHMARK ENVIRONMENTS.

4.1 DB2.

The DB2 portions of the benchmarks were run initially on a dedicated 3090-200 with 64 megabytes of real storage running the MVS/XA operating system at level 2.1.3. The DB2 software was release 1.2 The tables used in the study were loaded on 8 volumes of single density 3380 DASD which were distributed across 8 internal 3380 paths, 3 3880 controllers with 2 channel paths to each controller. Table 1. shows details of the various tables used in the benchmark. The tables were stored one per tablespace, in tablespaces that had been defined with the CLOSE(NO) option. Default values were accepted for the FREESPACE and FREEPAGES parameters. None of the tablespaces were partitioned. The RUNSTATS operation was performed for all of the tablespaces.

The sizes indicated are data sizes as opposed to allocated DASD space. The total DASD space actually allocated on the 8 volumes was approximately 3 gigabytes. The DB2 buffer pool BP0 was allocated at 24 megabytes, and 12 megabytes of BP1 were used for index buffers. In this environment we moved tables around until we achieved a reasonably balanced system with all DASD devices averaging 46.8% device active and two devices running at 86% device active over the peak 1 hour period in the batch query workload. During this 1 hour period the processor ran at 78% busy. Throughout all of the benchmark runs essentially no paging activity was measurable. As in many data centres where equipment configurations rarely remain constant, the 3090-200 processor was upgraded to a 3090-400 with 128 megabytes of real memory and 128 megabytes of expanded memory. This upgrade took place after the initial DASD balancing was completed. All the remaining data reported in this paper about DB2 CPU usage were derived from this final configuration.

4.2 Teradata DBC/1012

The benchmarks were run on a 8x24x24 DBC/1012 (8 IFP's, 24 AMP's, and 24 372 megabyte DSU's) connected to an Amdahl 5860 with the Multiple Domain Feature (MDF). The DBC/1012 was running the 042 level software with TDP release 2.3 running under MVS/SP 1.3. The MDF partition was assigned 15 megabytes of real memory and TARGET and MAX processor allocations of 20%. A second partition was running a VM system with TARGET and MAX processor allocations of 100% and 80% respectively. The equivalent indices as were used in the DB2 test were defined for the DBC/1012 benchmark runs.

4.3 Charging and Rate Setting

In companies which provide data processing services to their staff through internally operated facilities which employ a chargeback mechanism, it is often not the overall cost of providing the services to the whole organization that is of most interest, as are the charges which are billed to the individual users of the services. When conducting the benchmark it was important to be able to provide the users a comparison of the rates they could expect in each of the environments.

Table 1. Table and Index Descriptions

Great-West Life sets chargeback prices by projecting the annual cost for providing a resource such as a processor, and dividing it by the projected annual (chargeable) utilization of the resource. Utilization of resources by the data centre staff is considered non-chargeable The annual cost of a resource includes its depreciation, maintenance, cost of capital, floor space, environmental requirements, and required support staff such as operators and systems programmers. In the case of resources such as processors, other indirect costs are included such as those for disaster recovery, work scheduling, network and help-desk operation, and the provision of technical support to the user community.

In the case of the DBC/1012 while it was straightforward to estimate its direct costs, it was rather difficult to estimate the indirect costs and the projected usage of the resource. On the cost side, to maintain uniformity with the DB2 environment, the direct cost were loaded with the same proportion of indirect costs as were experienced for the DB2 host processors. As for the projected usage, an interesting phenomenon exists at Great-West Life. While the processing capacity of the data centre has grown consistently and dramatically over the past 5 years from a 3081 model D and a 3033 MP to a 3090 model 200 and 400, the chargeable utilization within any one year stays approximately constant at 20% of the theoretical maximum utilization of the installed processors. In estimating the price that would be charged for the utilization of a DBC/1012 the projected utilization of a processor was assumed to be 20% of its theoretical maximum.

In order to encourage the use of offshift capacity, Great-West Life offers a 50% price reduction for the use of processor resources outside of it 8 A.M. to 5 P.M. week-day prime usage period. The current situation is that 53% of all processor utilization takes place in the prime usage period with the remaining 47% taking place outside of the prime period. Again, the same assumptions were made in the determination of a DBC/1012 usage price. Although the DBC/1012 contains both SQL processing capabilities and storage capabilities, only the costs associated with the processor portion of the DBC/1012 were considered to make comparisons to the DB2 host environment credible.

Application of these pricing and projection policies resulted in a prime shift rate of $2160 for one hour of TCB and SRB CPU time as recorded by SMF ($1080 outside of prime shift) for the 3090-400, and $1995 and $1162 for one hour of processing time per processor on a 8X24X24 and 4X8X8 DBC/1012 respectively. The DBC/1012 maintains a separate set of system tables in which it accumulates the processor utilization necessary to operate this type of charging. These table can be can be queried and reset by the installation as necessary.

5.0 BENCHMARK RESULTS.

5.1 BATCH QUERY WORKLOAD.

The batch query workload was a selection of 13 intentionally long running complex queries which produced a relatively even distribution of device activity across the 8 3380 volumes used in the DB2 portion of the benchmark. In addition to running all 13 queries concurrently in a stand-alone environment, they were run serially to determine the degradation caused by query contention. Table 2 provides the elapsed time results of the 2 runs of the Batch Query workload. All times are given in seconds with the DB2 CPU times being the sum of the SMF reported TCB and SRB times. Estimated elapsed times are provided for an 8 AMP DBC/1012 configuration and were determined by multiplying the 24 AMP elapsed times by 3 based on Teradata's linearity claims. The host CPU time on the Amdahl system was so small as to be insignificant. Most of the queries, although long running, returned less thai, a 1000 rows which generated very low host consumption since the majority of processing was performed on the DBC/1012.

When compared to the 24 AMP DBC/1012, DB2's elapsed time was 5.9 times as long, and an estimated 2.0 times as long, for an 8 actuator sized DBC/1012 configuration. Running all the queries concurrently increased the DB2 CPU time by 10% over their serial execution, while reducing the total elapsed time for the whole job stream from a little over 19 hours to just under a 11.4 hours or a 68% reduction. The DBC/1012 configuration produced a 23% reduction in elapsed time from 3.3 hours serially down to 2.6 hours when multiprogrammed.

In a multiprogrammed environment an 8 AMP DBC/1012 was outperformed by DB2 by 40% on average, while a 24 AMP processor produces a 1.8 times improvement in responsiveness over DB2.

If one were to remove the 2 queries that DB2 had some difficulty in processing (Q02, and Q06) from the analysis, assuming that better indexing or query tuning could have brought their elapsed times down closer to the rest of the sample, the above relative performance ratios drop into the range of equality.

In order to compare the price performance of the two alternatives a projected chargeback algorithm was derived for the DBC/1012 environment. Similar assumptions were made for both the 3090 and DBC/1012 in developing the cost pools and anticipated usage for calculating the chargeback rate. In the Great-West Life environment a 50% rate reduction is given for the use of resources in the offshift. The resulting rates were applied to the CPU consumption of both systems and shown in Table 4 for an 8 AMP and 24 AMP DBC/1012 configuration respectively. The DBC/1012 was able to process this workload for between 17 and 27 percent of the DB2 cost on a 3090-400 depending on the size of the DBC/1012 configuration. The 24 AMP DBC/1012 resulted in the better of the two price performance percentages since it spread its fixed overhead over a larger usage base.

Table 3. Interactive Query Workload -- Projected User Charges

5.2 Interactive Query Workload.

The interactive query workload was a sample of 26 queries which had been developed by end-users who had been working in a decision support environment. The queries had been created using the IBM Query Management Facility (QMF) running on-line under the Time Sharing Option (TSO) of Multiple Virtual Storages Extended Architecture (MVS/XA) operating system. A short description of the SQL functions used in the queries and the EXPLAIN results can be found in Appendix A. It can be seen that significant use of indices is made in the execution of the queries.

Table 5. Interactive Query Workload -- Run Statistics

For purposes of the benchmark the queries were run using an IBM supplied dynamic SQL facility called DSNTEP22 in batch. In the Teradata environment the queries were submitted to a 24 AMP DBC/1012 using a Batch TEQUEL utility (BTEQ) which had similar function to DSNTEP22. All measurements were made in essentially standalone mode running the queries sequentially. Table 5 shows the elapsed time results for the two benchmark environments and an estimation of an 8 AMP DBC/1012 environment. The 8 AMP DBC/1012 environment was included to compare the two environments where an equal number of actuators were available to support the processing. In total the DBC/1012 outperformed DB2 by a factor of 4.88 to 1 in elapsed time. However, the performance improvement was greatly skewed toward long running requests. In requests where the DB2 elapsed time was approximately 10 minutes or less the 24 AMP DBC/1012 was outperformed by DB2 on average by approximately 11%, whereas on the longer running queries the DBC/1012 performance was more than 5 time better than DB2.

From a chargeback perspective, DB2 costs were approximately equal to those from an 8 AMP DBC/1012, but the 24 AMP DBC/1012 would have generated only 65% of the DB2 charge as shown in the On-Demand Charges portion of Table 3. If one was to assume that queries running over an hour in either environment would be scheduled off-shift and take advantage of an off-shift pricing differential (which might be a reasonable assumption in a budget constrained organization employing chargeback) then the 24 AMP DBC/1012 cost are 7% greater than DB2's and the 8 AMP DBC/1012 costs would be 15% greater as shown in Charges with Deferred execution portion of Table 3.

5.3 Transaction Processing Workload.

In order to investigate the transaction processing power of the two systems a set of synthetic kernels were used. These kernels used the various relational operations of insert, update, select, and delete. These were used in combination with varying degrees of set processing against both clustered and non-clustered rows. In addition, attempts were made to determine the cost of commit processing for each of the operations. All of the kernels operated on the COVR table which had 6 indices defined on it. One of these was a unique clustering index and the other 5 were non-unique and non-clustering. All of the kernels accessed the table through the unique index.

The various kernels were submitted as separate batch job steps using the DSNTEP22 program and BTEQ in the DB2 and DBC/1012 environments respectively. No true transaction driver such as CICS or IMS was used to generate the workload for this portion of the benchmark. Great care was taken in the order of execution of the INSERT and UPDATE kernels to insure that the table would retain its clustering and not require refreshing after each sequence.

For this portion of the benchmark the DB2 buffer pools were reduced significantly. It would have been unrepresentative to have used the larger buffer pools without having had significant levels of concurrent transaction processing. Since generating a heavy concurrent transaction workload with facilities such as IMS or CICS would have greatly increased the complexity of transporting the benchmark, the smaller buffer pool strategy was chosen to, in effect, make DB2 churn buffers with single thread transactions. The DB2 parameters were set to provide 20 data buffers in BP0 and 10 index buffers in BP1.

It should also be noted that all requests used the DB2 dynamic SQL facilities which implies that the overhead of developing an execution plan was incurred for every SQL statement processed. In a true transaction processing environment static SQL would undoubtedly be used. This decision was again made to increase the portability of the benchmark to the Teradata benchmark facility.

5.3.1 Delete operations.

Three streams of delete operations were performed. The first deleted increasing numbers of clustered rows from a table. The second run deleted increasing numbers of unclustered rows. The third run was the same as the second except that commits were inserted between each delete operation. The results of the three runs are shown in the sections of Table 6.

In the DB2 environment delete operations require approximately 23 ms ((3.12-.26)/127)of 3090-400 SMF recorded CPU time to delete a clustered row, reaching a throughput of approximately 1.7 rows deleted per second as the size of the set deleted increased. The DBC/1012 managed to deliver set deletes at a maximum throughput of 2.3 rows per second. In the unclustered delete operations the DBC/1012 just slightly outperformed DB2 when commits were deferred to the end of the logical transaction but showed a marked slow down when commits were performed after each row deleted.

Rows Deleted	DB2 CPU sec	DB2 Rows/ CPU sec	DB2 Elapsed sec	DB2 Rows /sec	DBC Elapsed sec	DBC Rows /sec
Clustered rows set deleted						
1	0.26	3.9	0.9	1.07	1.0	1.1

4	0.32	12.5	2.6	1.52	2.7	1.5
8	0.41	19.5	4.8	1.67	3.5	2.3
16	0.60	26.7	9.7	1.65	7.0	2.3
32	0.97	33.2	18.7	1.71	15.0	2.1
64	1.70	37.8	36.3	1.76	27.5	2.3
128	3.12	41.1	73.9	1.73	56.5	2.3
Unclustered rows with one commit per row						
1	0.26	3.9	0.9	1.07	1.0	1.1
2	0.32	6.3	1.8	1.13	0.7	2.9
4	0.46	8.7	3.7	1.07	2.3	1.7
8	0.74	10.8	7.6	1.06	6.0	1.3
Unclustered rows with one commit per set of rows						
1	0.26	3.9	0.9	1.07	1.0	1.1
2	0.33	6.1	2.2	0.89	1.3	1.5
4	0.47	8.5	3.7	1.09	4.0	1.0
8	0.77	10.4	7.9	1.01	8.0	1.0

Table 6. Transaction Benchmark - Delete Results

5.3.2 Insert operations.

Four streams of insert operations were performed. The first two performed clustered set inserts on increasing numbers of rows. The second of these included commits after each insert operation. The last two runs were similar to the first two except they operated on rows which were not clustered. Their results are shown in Table 7.

The clustered inserts required 73 ms/row of SMF recorded 3090-400 CPU time with the deferred commits, and 82 ms/row with commits for each insert. By taking the differences in CPU time between the first and second runs the commit overhead can be calculated to about 9 ms. Both DB2 and the DBC/1012 leveled off to approximately 1 row inserted per elapsed second with DB2 being just a little faster. Throughput dropped by a factor of approximately 3 for the DBC/1012 when the inserts became unclustered.

5.3.3 Select Operations

Two runs were made for select processing. The first shows the effect of increasing the number of rows in clustered selects, with the second run performing the same sorts of operations but on unclustered rows. The results are shown in Table 8.

The DB2 system uses about 3 ms/row to select clustered rows and 6 ms/row of SMF recorded 3090-400 CPU time to select unclustered rows. In terms of responsiveness, DB2 far outperformed the DBC/1012 by factor of at least 7 to 1. This was somewhat of a mystery considering that the DBC/1012 compared favourably on most of the other kernels.

5.3.4 Update operation.

Three runs of updates were performed. The first run performed clustered set updates on increasing number of rows. The second run performed updates of increasing numbers of unclustered rows, while the last one added commits between each row update. The results are shown in Table 9.

DB2 uses approximately 8 ms/row of 3090-400 SMF recorded CPU time to update clustered rows with set operations. This can be contrasted with 154 ms/row and 168 ms/row for unclustered updates depending on where the commits are processed. From the response point of view the DBC/1012 and DB2 function approximately the same, with both showing almost a 10 times increase in response time for unclustered updates:

Facilities such as LOCK TABLE were not used before running the update kernels. It was felt that use of these facilities, which can notably improve update performance, would not have been representative of a transaction environment which would have to support a combination of concurrent update and retrieval operations.

Rows Inserted	DB2 CPU sec	DB2 Rows /CPU sec	DB2 Elapsed sec	DB2 Rows /sec	DBC Elapsed sec	DBC Rows /sec

Table 8. Transaction Benchmark - Select Results

5.3.5 Transaction Processing Cost.

In terms of transaction oriented responsiveness the DBC/1012 and DB2 are relatively equal with the exception of SELECT processing. However, in terms of the chargeback cost to accomplish those same operations the DBC/1012 is significantly more attractive. The Table 10 shows the relative costs of performing each of the four basic operations on 255 rows of data. Depending on the size of the configuration the DBC can be about 2 to 4 time more cost effective.

Rows Updated	DB2 CPU sec	DB2 Rows /CPU sec	DB2 Elapsed sec	DB2 Rows /sec	DBC Elapsed sec	DBC Rows /sec
Clustered set updates

Table 10. Transaction Benchmark - Charge Comparisons

5.4 Table Loads.

In the DB2 environment the tables were loaded specifying LOG=NO. The release of the DBC software used in the benchmark, provided only a transient transaction log capable of backing out in-flight transactions in the case of hardware or software failure. Table 11 show the results of the load processing in both environments. The CPU time and elapsed time for the creation of all indices associated with a table are included in the numbers for each base table.

DB2 performed better than the DBC/1012, but neither of them were particularly snappy at the job. It took 14 and 18 hours respectively to load about 3 gigabytes of data and indices which is rather difficult to cope with, considering the over-night batch processing windows many shops face. Load times of this duration also make the regular testing of disaster backup procedures very difficult.

Table Name	Table Size in MB	000's Of Rows	DB2 Host CPU Seconds To Load	DB2 Rows/ CPU Second	DB2 Elapsed Seconds To Load	DBC Elapsed Seconds To Load	DB2 Rows/ Elapsed Second	DBC Rows/ Elapsed Second	Elap. Ratio DB2/ TD

Table 11. Comparison of Table Load Performance

5.5 Secondary Index Creation

The parallel processing power of the DBC/1012 showed through in the area of secondary index creation after table load. This is shown in some samples of index creation performance measures in Table 12. The DBC/1012 outperformed DB2 over 4 to 1 in elapsed time.

Table 12. Comparison of Secondary Index Creation Performance after Table Load

6.0 CONCLUSIONS.

When considering a wide variety of workload situations, neither the software nor hardware based relational data-base processing systems appears as a clear performance winner. The two systems benchmarked in this paper each has its own particular strengths. DB2 was shown to outperform the DBC/1012 especially in the area of small decision support query applications and somewhat in the transaction processing area. The DBC/1012 strong suit is in the area of large table scans which are likely to be the realm of complex decision support and analysis systems where it can use its parallel processing muscle.

An 8X24X24 DBC/1012 appears to be approximately equal to the performance of a 3090-200 in processing complex concurrent batch queries at about one quarter the cost. When processing simple interactive queries the 24 AMP DBC/1012 performs comparably to DB2 when no multiprogramming takes place. It is likely, given the degradation patterns shown from the batch query environment, that a much larger DBC/1012 would be necessary to match the capabilities of a 3090-200 for simple interactive query workloads.

7.0 ACKNOWLEDGEMENTS.

The authors would like to thank Pat Gowryluk for his efforts in preparing the data used in the benchmark, his help in explaining the operational environment in which the queries were used, and the actual running of the queries during the benchmark. As well, much gratitude is owed Craig Essex, for without whom, none of the preceding data would have been available for analysis.

PERFORMANCE TUNING FOR A VAX-BASED RELATIONAL DATABASE APPLICATION: A CASE STUDY AND LESSONS LEARNED

G. Burgess Allison
The MITRE Corporation

ABSTRACT

This paper describes the steps taken to optimize performance of a relational database application. The application is intended for correspondence management; it is strongly retrieve-and-display oriented; and it was initially designed to support interactive access to approximately 50,000 logical records by a limited number of users. The processing environment is a VAX cluster, with Relational Technology, Inc.'s INGRES as the application DBMS. The paper includes a description of the performance-related problems encountered, the system design approaches that were adopted during application development, and the implementation-level approaches that were incorporated while the system was in use. Performance was significantly improved without modifications to either the hardware or DBMS: queries against an initial 53-record test data base failed to complete in 23 hours; the average append and retrieve response times on the production system was lowered to 11 seconds. The paper concludes by identifying several key factors that can dramatically affect performance in a relational database application.

1. INTRODUCTION

The relational data base model is currently enjoying widespread popularity. Indeed, there are several compelling advantages to the relational model; hardware and software vendors are emphasizing relational capabilities; and performance improvements in relational products recently prompted the acknowledged originator of the relational model, E.F. Codd, to conclude, "nonrelational DBMSes have finally become obsolete!"[1]

Regardless of arguments for and against the relational model, many application developers and prototypers are finding themselves in situations where they *must* use a relational DBMS; and there are some applications that produce dramatically poor performance when implemented in a relational environment.

This paper presents a case study of just such an application—initial test queries failed to complete in 23 hours—together with the techniques that were used to improve performance to acceptable levels. Some of the techniques used violate basic principles of the relational model; some are traditional performance tuning techniques; and a few are specific to the DBMS used. In the production system eventually implemented, the average response time was reduced to 11 seconds.

Some of the experience from this performance tuning process was undoubtedly unique to the application. However, some of the techniques and results may have more general applicability and may be of use to developers and designers who are faced with the task of implementing similar applications in a relational environment, or who have an opportunity to select the data base model to be used. It will be the purpose of this paper to focus on the experience with such general applicability.

1.1 BACKGROUND

The application discussed in this paper was developed to provide automated assistance in the process of correspondence management for a large Federal agency. This process includes: review and distribution of all incoming mail; assignment of responsibility for answering significant correspondence; tracking the progress of such assignments; and coordinating the generation, review, and signature of outgoing correspondence. The automated components of this process include: storage of information contained in the correspondence; tracking of assigned responses and outgoing correspondence; and retrieval of archives data in response to ad hoc inquiries.

The correspondence and files unit (CFU) of this particular agency[2] was already using an automated system to assist in correspondence management activities. The existing system was proprietary, and was maintained on a dedicated minicomputer. A new automated correspondence management system (ACMS) was intended to replace and upgrade the proprietary system—as an application on the agency's Digital Equipment Corp. (DEC) VAX cluster, using Relational Technology Inc.'s INGRES relational data base management system (DBMS). Thus, the development project included two phases: pre-implementation and post-implementation. The ACMS is currently operational in a production environment.

1.2 PURPOSE

This paper documents the steps that were taken to optimize performance of the ACMS. The paper describes the performance-related problems that were encountered, the system design approaches that were adopted during application development to optimize performance, and the implementation-level approaches that were incorporated while the system was in use. The rationale for each approach and the performance tests conducted for each are also described.

Since this is a case study, it is not the purpose of this paper to define an ideal performance optimization process; rather the purpose is to record what was actually done. Indeed, there were instances during the project when limited resources precluded extensive pre-testing; when decisions were made because a conclusion was "intuitively obvious"; and when time constraints—caused by trying to conduct performance tuning on an operational system—dictated short-cuts in the construction of tests and in the control over test conditions. Still, in many cases the findings are clear, and alternative approaches that were identified during post-project review are presented in the last section as lessons learned.

1.3 SCOPE

The scope of performance optimization in this project was expressly limited to application-level programming, using only documented INGRES features in a VAX cluster environment. Also, the ACMS was implemented as one of several applications running on the VAX cluster;

---

[1] Codd, E.F. "1987: The Beginning Of A New Era In Data Processing," InformationWEEK, CMP Publications, Inc., Manhasset, NY, May 4, 1987.

[2] The identity of the Federal agency involved is immaterial to the issues under discussion; in the absence of a compelling reason, the identity will not be disclosed.

there was no provision or intention to provide the ACMS application with any "special" status. Consequently, performance tuning in this project was not to include any of the following: "tuning" the VAX to maximize performance of INGRES applications; use of undocumented INGRES features; or modifications to the VAX hardware, the VMS operating system, or INGRES.

Accordingly, the scope of this paper is limited to decisions and approaches at the system design and implementation levels.

1.4 ORGANIZATION OF PAPER

The organization of this paper is as follows:

- Section 2, "SYSTEM DESCRIPTION," describes the environment within which the ACMS operates. This includes hardware and software in the application development environment, and application-level constraints shaped by users and user requirements.
- Section 3, "SYSTEM DESIGN FACTORS," describes performance-related problems that were encountered prior to implementation, the system design factors and alternatives that were considered for resolving each performance problem, and the specific system design approach that was used to resolve each problem.
- Section 4, "IMPLEMENTATION-LEVEL FACTORS," describes the performance problems that were reported in the operational ACMS, the implementation-level factors that were determined to have a significant impact on performance, and the specific techniques and modifications that combined to resolve the performance problems.
- Section 5, "SUMMARY," describes findings from the ACMS performance tuning efforts, and describes general conclusions that may be drawn from these findings.

2. SYSTEM DESCRIPTION

This section describes the environment within which the ACMS operates. This includes hardware and software in the application development environment[3], and application-level constraints shaped by users and user requirements.

2.1 APPLICATION DEVELOPMENT ENVIRONMENT

The ACMS application development and operations environment is illustrated in Figure 1. As shown, the ACMS operates on a pair of DEC VAX minicomputers, connected through DEC's DECNET VAX-cluster hardware and software. The operating system is DEC's VMS. The standard user interface adopted on the VAX cluster is DEC's ALL-IN-1 Office Automation system, and all applications are invoked from an ALL-IN-1 menu.

The ACMS is an INGRES Application-By-Form (ABF) application, using FORTRAN-based Embedded Query Language (EQUEL) programs as ABF procedures and Query-By-Form (QBF) definitions as ABF frames. All forms are defined using INGRES' Visual Forms Editor (VIFRED). EQUEL is a preprocessor which produces VAX VMS FORTRAN source code with appropriate calls to the INGRES DBMS library functions. FORTRAN programs are written by the application developer with specially formatted INGRES statements, and are submitted to the EQUEL preprocessor as input. QBF is a development tool which generates components of an application (such as append, update, and delete) based on a definition of components (e.g., VIFRED form name and INGRES table name) supplied by the application developer. ABF is a menu-driven environment that coordinates user access to EQUEL and QBF modules.

There are several connectivity options that define the ACMS user environment: direct connection to the VAX-cluster DEVELCON switch, which permits the user to log on to either of the two VAX minicomputers; asynchronous connection to the DEVELCON switch, through either dial-up modems or the agency's wide-area network; and asynchronous connection to the wide-area network, through dial-up modems. In all cases, the user must respond to the DEVELCON switch prompts to select a host and must complete the necessary VMS log-in procedures on the selected host. Access is provided to the user at a start-up ALL-IN-1 menu and the ACMS is invoked by a command from the ALL-IN-1 command line.

Direct connection to an individual VAX minicomputer is possible, but is strongly discouraged by VAX systems personnel since it precludes logging onto the "other" VAX and thereby eliminates many of the advantages of the cluster environment.

User workstations include VT220 terminals and DecMate II communicating word processors.

Specific capacities of the hardware, and specific release and version numbers of the software are not shown because it was an express objective that the ACMS would be independent of such factors. Indeed, through the course of the project, VAX memory and disk storage units were changed, the operating system was upgraded to a new major release, and ALL-IN-1 was upgraded to a new major release. Major new releases of INGRES were also installed. These changes, and their effects, will be discussed in appropriate sections of this paper.

2.2 APPLICATION REQUIREMENTS

The correspondence and files unit (CFU) processes more than 40,000 pieces of mail each year. Each piece of correspondence is reviewed by an analyst. All items that require action are recorded and assigned for response. Also, some of the correspondence is judged by the analyst to be "significant," irrespective of a need for action or response, and is recorded for archival and reference purposes. The CFU is responsible for assigning and tracking the progress of responses, for coordinating all outgoing correspondence, and for responding to questions regarding past or pending correspondence.

The ACMS was developed to support three specific functional requirements:

- Record Keeping—storage and update of correspondence data (abstracts and relevant tracking information)
- Tracking—management reports to assist in the tracking of responses
- Reference—selective retrieval of individual correspondence records

A single data form is sufficient to accept correspondence input, to update records, to specify search criteria, and to review retrieved records. For these entry and reference purposes, the full correspondence record is required.

---

[3] The descriptions of systems and products currently in use do not represent endorsements of the product lines or vendors mentioned. We are in no way suggesting them as recommended configurations, nor are we commenting on their relative strength as compared with other possible configurations—available from other vendors, or from the same vendor.

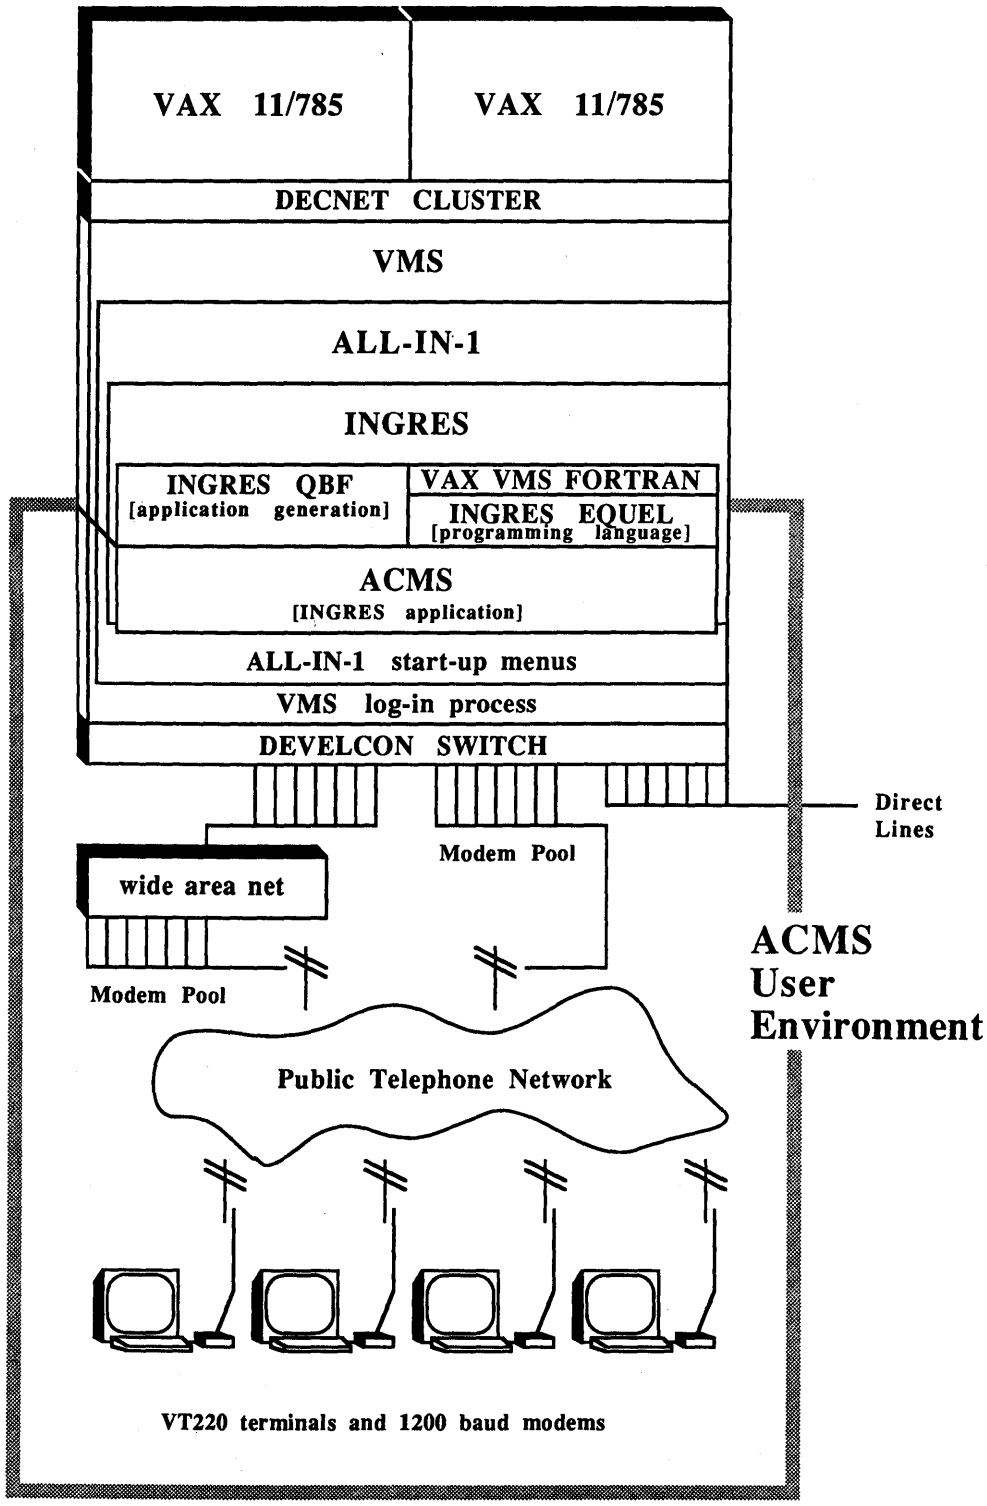

Figure 1. ACMS Application Development Environment

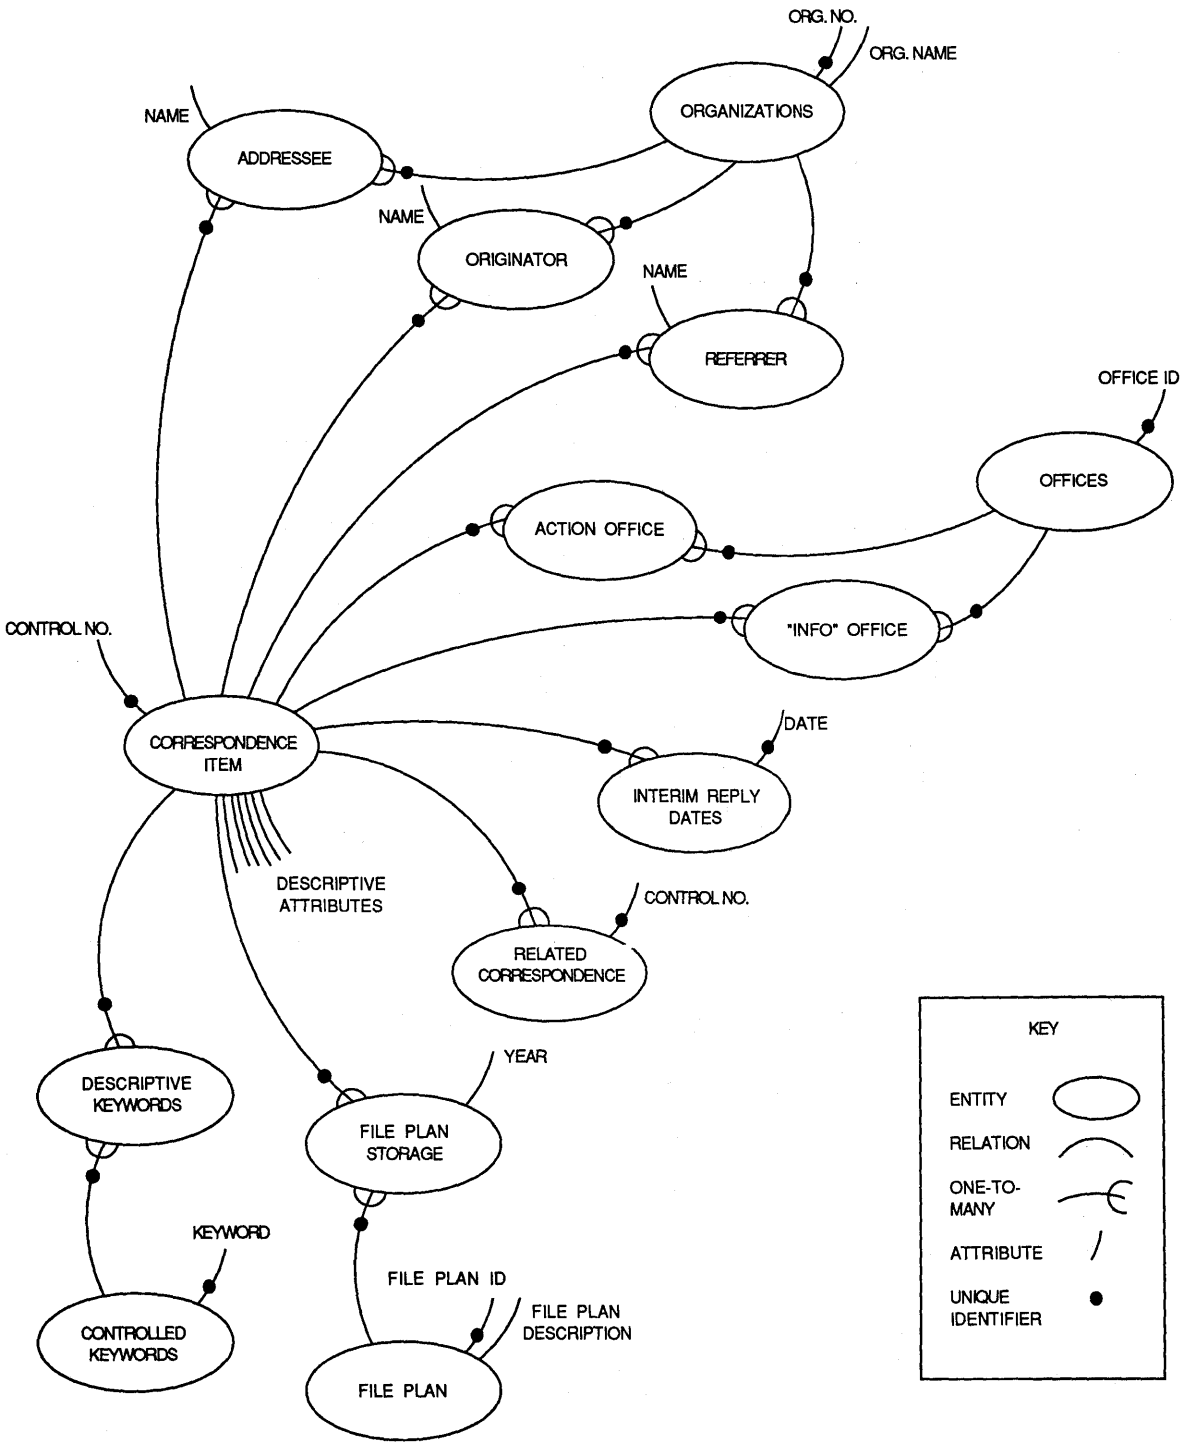

Figure 2. ACMS Data Structure Diagram

Due to the nature of inquiries for information on specific items and classes of correspondence, the retrieval function must be flexible enough to identify qualifying correspondence from partial information (e.g., author, date, subject), and it must be responsive enough to be considered interactive. Specific system-related and performance requirements were identified as follows:

- Archival volume: 50,000 records through 1985.
- Transaction volume: 6,000 to 10,000 records per year.
- Record structure: includes "repeating fields" or "multiples"—a record might show several authors, several keyword descriptors, or several "interim" replies. Analysis of user requirements indicated that there were nine such repeating fields (see below).
- Record size: approximately 1750 characters, depending on occurrence of repeating fields.
- Response time: specified in requirements documentation as, "an interactive process: movement among different modules within the application must be accomplished in a few seconds; pre-defined system operations must be accomplished within 10 to 20 seconds."
- Data entry: some fields require character validation; some fields require table lookup validation; and one field—the correspondence control number, which was defined as the data base primary key—must be unique and automatically assigned by the application.

In retrospect, two of these requirements proved to have a pivotal impact on the performance of the application in a relational environment: the record structure, and the users' need for access to logical records.

For each logical record, there are nine fields and groups of fields which can have multiple entries:

- addressee—the correspondence may be addressed to more than one person. This information includes each addressee's name, and a unique code number for the addressee's organization.
- originator—the correspondence may have been sent from (or signed by) more than one person. This information includes each originator's name and organization code number.
- referrer—the correspondence may have been referred from (or through) more than one person. This information includes each referrer's name and organization code number.
- keyword—the subject matter of the correspondence may be described with several descriptive keywords, taken from a controlled vocabulary.
- action office—responsibility for responding to an item of correspondence may be assigned by the CFU to more than one office within the agency.
- information office—the CFU may forward "information only" copies to several offices within the agency.
- interim reply dates—the CFU or action office(s) may send several interim replies to the correspondent, providing information about the progress of a response.
- related records—the item of correspondence may be related, by subject matter, to other items in the ACMS. The identity of related correspondence is recorded using the CFU control number (primary key).
- "file plan number"—the physical copy of the correspondence is stored in physical files on the basis of a content-sensitive filing system (known as a "file plan") similar in function to the Dewey Decimal System used in libraries. A single item of correspondence may be copied and stored under several file plan numbers.

Strictly adhering to the relational model, the resulting data structure includes 14 separate relational schemas, as illustrated in the data structure diagram in Figure 2. (The diagram does not show fields—or "attributes"—that are simply descriptive in nature.)

A second key requirement was the users' need for access to *all* the information related to a particular item of correspondence, whenever that item was accessed for update or reference. Simply put, the users expressed a strong and certain need for access to the entire logical record: the nature of the inquiries handled by the CFU demanded retrieval of all relevant data, and dividing the retrieval process into several "partial" steps would interfere with the office's work to an unacceptable extent.

How these factors affected performance in a relational environment will be discussed in the next section.

3. SYSTEM DESIGN FACTORS

This section describes performance-related problems that were encountered prior to implementation, the system design factors and alternatives that were considered for resolving each performance problem, and the specific system design approach that was used to resolve each problem.

The principal problem areas encountered include: implementation of the ACMS record structure in a relational data base environment; the amount of ACMS data; the choice of an INGRES application development tool; and the choice of an INGRES data base structure.

All of the pre-implementation performance problems encountered were resolved prior to implementation, and the response times achieved in the development account were within acceptable ranges. Tests conducted in user accounts—through the ALL-IN-1 interface—also produced acceptable results. Terminals were installed in user offices, training was conducted, conversion of data from the existing correspondence management system was completed and the ACMS was implemented as an operational system. Performance problems encountered and resolved after implementation are discussed in Section 4.

3.1 RELATIONAL STRUCTURE OF LOGICAL RECORDS

The relational structure of the ACMS logical records represented the single largest factor having a negative impact on performance. Queries against an initial 53-record test data base would not complete in 23 hours, and would occasionally cause the VAX process to fail—requiring restoration of the entire data base.

The problem was attributable to the implementation of the ACMS "repeating field" record structure in a relational data base. While it is commonly held that the relational model can be used to emulate many different types of data base structures, the use of several related tables to implement repeating fields had a negative and dramatic impact on performance.

The approach used to resolve the problem was to implement most repeating fields by limiting the number of

possible repetitions and defining a separate field for each such repetition. Although the first-normal-form constraint[4] of the relational data base model is not technically violated using this technique, the underlying principles are unequivocally defeated. Under the circumstances, however, the approach was deemed necessary.

3.1.1 Problem Conditions

The initial test data base used 8 related tables[5] and a single primary key[6] that uniquely identified logical records. One of the tables was treated as a "master" table; it contained non-repeating data that pertained to a single item of correspondence (e.g., abstract, date written, date received). The primary key to the master table was defined as unique (i.e., no duplicate keys). The 7 other tables represented "detail" tables; they contained data pertaining to a single item of correspondence for which there might be multiple entries. The primary key for all detail records was the same as that for the related master record, thereby defining a logical ACMS record. Since there would be multiple detail records, duplication of primary keys was permitted in the detail tables. The master table contained 45 fields representing approximately 1500 characters; the 7 detail tables contained 1 to 3 fields each, ranging in length from 1 to 60 characters.

An initial test data base was constructed with 53 logical records—each having a single master record, and most having at least 2 detail records in each of the 7 detail tables. The number of detail records ranged from 1 per detail table to 7 per detail table.

A simple query was constructed to join the eight components of the logical ACMS records (using the common primary key) and to retrieve individual records for review. Response times varied dramatically, depending on the number and distribution of detail records. Logical records with the fewest number of detail records were retrieved in a few seconds. Logical records with high numbers of detail records (e.g., 7 records in each of 7 detail tables) could not be retrieved. Queries for some records would continue until the process was terminated for daily backup procedures (all user-processes on the VAX cluster are terminated each night for backups—the longest attempted query was allowed to run for a total of 23 hours.) Queries for some records would cause INGRES to fail completely and the data base would have to be restored.

Analysis of the relational record structure demonstrates why this occurs.

When a relational join is used to retrieve a logical record from related tables, the data base retrieves a set of de-normalized data (multiple records). For example, if a master record is joined with a related "keyword" table that has 2 qualifying records, the join produces 2 separate records: one showing all the data from the master record plus one of the keywords, and another showing all the master data with the other keyword.

domain of Join =	(master	keyword)
	m_1	k_1
	m_1	k_2

If the master and keyword tables are joined with a related "referral" table that has 3 qualifying records, then the join repeats the master/keyword pair 3 times—once for each referral—producing a total of 6 records.

domain of Join =	(master	keyword	referral)
	m_1	k_1	r_1
	m_1	k_1	r_2
	m_1	k_1	r_3
	m_1	k_2	r_1
	m_1	k_2	r_2
	m_1	k_2	r_3

The total number of records that will be retrieved from a relational join is the product of the several record counts for each of "n" detail tables. Where D_n is the record count for detail table n, the total number of records retrieved in a join for a single logical record is:

$$\text{"join" records} = (D_1) \times (D_2) \times (D_3) \times \ldots \times (D_n)$$

With the structure and data of the test data base—8 related tables with as many as 7 records in each of 7 detail tables—the total number of de-normalized records retrieved for the largest logical record was $(7)^7$, or 823,543 total records. With approximately 1750 characters per logical record, the total amount of data that had to be handled to retrieve that one logical record was 1.44 gigabytes.

Two factors combine to produce the observed performance problem: the number of related tables has a severe impact on the amount of data that must be handled during even simple retrieves; and the relational join is responsible for the multiplicative effect of related tables.

3.1.2 Reduce the Number of Related Tables

The first part of the solution was to reduce the number of related tables. The multiplicative effect of even a small number of such tables (combined with an INGRES limitation[7]) strongly suggested that the number of related tables be reduced to one. Also, the nature of the ACMS usage indicated that one particular field (keywords) would have much greater utility as a "repeating" field than any other data element. Based on these considerations the number of related tables was reduced to one: keywords.

Two different techniques were used to eliminate the remaining repeating fields, depending primarily on anticipated data element usage.

For data elements that are part of repeating groups of fields, or where a structured data entry format is highly valued (such as fields that are likely to be used as search criteria), repeating fields were implemented by selecting a limit to the number of repetitions that would be permitted, then defining that many iterations of the field in the master table. For example, it was determined that three file plan numbers would offer a sufficient number of repetitions and the master record data dictionary was modified to include three separate file plan fields: file_plan1, file_plan2, and file_plan3. This approach permits structuring and validation of entered data, but it also means that a user searching for occurrences of a particular file plan number, for example, would have to repeat the search

---

[4] Each record, or "row," may have only one value for any given field, or "attribute."

[5] The initial test data base was constructed without use of separate tables for "interim reply dates" or "related records."

[6] The correspondence control number was the primary key.

[7] INGRES limits the numbers of related tables that can be displayed on-screen at one time: only one related detail table, referred to in INGRES as a table field, can be displayed on-screen with corresponding master records.

three times: specifying the qualifying criteria in each of the three repeated file plan fields.

For data elements that are likely to be used most for reference (rather than retrieval) purposes, where structured data entry format is less important, repeating fields were implemented by defining a single large field—sufficiently large to permit inclusion of several entries. This single-field approach increases the flexibility for storing multiple entries, but is not conducive to data structuring or validation. Searching such a field is accomplished primarily through the use of bracketing wildcards (e.g., where interim_date = "*10/15/86*").

3.1.3 Reduce the Use of Relational Joins

The second part of the solution was to reduce the use of relational joins wherever possible. Specifically, joins can be eliminated in the basic process of accumulating and displaying the logical record. Also, the effect of joins can be substantially reduced in the query process by retrieving only one field—the primary key; thereby limiting the use of joins to situations when the user specifies both keyword and master-record qualifying criteria.

To accomplish these objectives, the retrieval of logical records is divided into a two-part process: each user-specified query retrieves only the primary keys of qualifying logical records, then the primary keys are used to retrieve the contents of the master record and the related keyword records. The query portion of the retrieve is optimized because it needs to handle less data, and because it can be run only against the master table, or only against the keyword table. The data-accumulation portion of the retrieve is optimized because it relies exclusively on primary key retrieves—the fastest available.

A cost of this "split retrieve" approach is that it requires multiple accesses to the data base for a single functional retrieve. This would cause a problem if large groups of logical records had to be retrieved and displayed at one time: the retrieve request would be effectively doubled as the DBMS retrieved 25 primary keys, then retrieved the 25 logical records.

However, the split retrieve approach is feasible in the ACMS because the CFU's "record-keeping" and "reference" functional requirements dictate a need to view logical records one at a time, sequentially accessed—analogous to scanning pages in a book. Thus, the primary key retrieves are distributed over several screen changes in a single viewing session, and many of the qualifying records are not retrieved at all if the user finds the desired information in one of the first records viewed.

A second factor in the feasibility of the split retrieve approach is the programmability of EQUEL-based INGRES applications (other INGRES application tools[8] do not support split retrieves). Sets of primary keys are stored in FORTRAN arrays, then processed upon user action to retrieve the necessary logical records. Also, the implementation of split retrieve processing in a programmable environment offers other operational advantages, such as reporting counts of retrieval "hits," and giving users the flexibility in reviewing retrieved records (i.e., program-controlled retrievals either "forward" or "backward" through the primary key array).

---

[8] The other application development tools are comparatively easy to use, but make exclusive use of relational joins. Interestingly, these tools—which impose an inherent performance burden—are often pivotal in attracting users and developers to a particular relational DBMS, based on ease of use.

3.1.4 Other Alternatives Considered

A more traditional approach to reducing the use of relational joins is to avoid retrieving data from related tables. This approach is based on the premise that the content of a logical record (i.e., what data elements the user needs to access) depends on what the user is doing. An example of this can be found in a parts data base: if a user is reviewing part numbers and descriptions, there is no need to access pricing, procurement, or inventory data from related tables—and no need to invoke the implicit relational joins. Joins in such an example would be required only when the user explicitly wishes to review a particular subject area.

In the ACMS, however, the functional requirements dictated user-access to all data pertaining to a particular item of correspondence. Only one functional requirement—tracking of assigned responses—might be satisfied through access to a subset of the data elements, but the tracking function subsets are already set aside in reports and only one of the possible repeating fields would be used in the tracking function.

3.2 DATA BASE SIZE

The size of the ACMS data base also had a severe impact on performance. Specifically, any query that produced a sequential search (i.e., any search for a value in a non-key field) required approximately one minute of searching for every 3,000 logical records—on a completely unloaded VAX user running only the one test process. With a data base size of 50,000 records, this "ideal conditions" response time of 17 minutes was unacceptably long.

The solution to the problem of data base size was a function of dividing the ACMS data into manageable data sets, thereby reducing the number of records searched at any one time. Because of the nature of data usage, different mechanisms had to be developed for dividing older, "archives" data and more active, "current" data.

The division of data was done on the basis of a single attribute: "closing" of the correspondence item (e.g., sending a response, if a response was required). Archives data was divided into single-year data sets, based on the date closed. Access to archives data is provided by temporarily loading archives data (from tape, at user request) into a designated INGRES archives table. Current data was divided into "open" and "closed" data sets. The open/closed division leaves a fairly large "closed" data set, but the number of transactions against the much smaller open table was expected to represent the majority of transactions, thereby substantially reducing response times for "most" transactions.

3.2.1 Problem Conditions

The size of the ACMS data base was defined by past usage of the existing automated system. As of 1985, the total number of stored records was 50,000, and the annual rate of increase had been increasing steadily since the system had been installed in 1978. The most recent years' experience indicated an average annual rate of approximately 8,000 records per year, ranging from 6,000 to 10,000. Although modest increases in the rate of growth were considered possible, the average of 8,000 records per year was judged by users to be an accurate estimate, and comparatively stable.

Because of the frequency of "reference" requests for past correspondence, the user requirements for interactive access were determined to span 2 to 3 years of data (16,000 to 24,000 records).

Tests that were used to select an INGRES data base structure (see Section 3.4, below) also indicated that

retrieval times against a table containing 20,085 records could be as long as 7 minutes, even under "ideal" conditions. Specifically, the tests performed a range of searches (including exact matches, wildcards, different sized targets) against a non-key field in the master table. The tests were comprised of FORTRAN-based compiled programs (EQUEL), and were conducted with no other users on the VAX cluster. Response times ranged from 7:04 to 8:02 minutes (noted in minutes:seconds).

While these tests provided useful information for comparing different data base structures, they also revealed lower limits for response times. Experience indicated that loaded-system response times could be expected to be at least 2 to 3 times longer than the unloaded-system ideal times. Extrapolation suggested that the best-case response time of 21 seconds per thousand records would translate to an effective response time of 45 to 60 seconds per thousand. For a 50,000 record data base, the implied sequential search times of 40 to 50 minutes were judged unacceptable.

One additional factor served as a constraint on possible approaches: limited data storage on the VAX cluster. Specifically, the estimated 150 megabytes required for a 50,000 record data base (including application software) was almost double the amount that could be set aside for the application.

3.2.2 Implemented Solution

The solution was to divide the data base, thereby reducing the number of records to be searched at any one time. Mechanisms had to be developed for dividing the ACMS data into more manageable sets, then providing ad hoc access to any single set. Two different mechanisms were developed: one for "archives" data, one for "current" data.

3.2.2.1 Division of Archives Data

The archives division dealt with data that was older than the 2-to-3 year limit set by users for immediate access. This mechanism for division also had to be responsive to the data storage limit.

The ACMS archives data was divided into single year data sets, according to the value of the date_closed field (a correspondence item is "closed" when a response has been sent or, if no response was required, on the date received). A procedure was developed to remove archives data from the "current" tables on an annual basis, and the cutoff date for the date_closed field would be set so the remaining current records would include two years data. For example, on January 1, 1990, the archives for 1987 would be removed, leaving all ACMS data from 1988 and 1989. Throughout 1990, the amount of "current" data would increase (approaching three years' data), and on January 1, 1991, the archives for 1988 would be removed—again leaving two years' data.

The mechanism for providing access to archives data was to store all archives on tape, to establish an INGRES archives table pair ("amaster" and "akeyword," representing both master and keyword records), and to load individual archives from tape into the archives table pair upon user request. The application would employ a separate command for running search criteria against the archives table pair.

Once a desired archives year was on line, the data would be accessible within 6 to 8 minutes for sequential searches (based on an expected archive data base size of 8,000 records). If the desired archives had to be loaded from tape, there would be a delay of at least several hours. These conditions were judged by users to provide an acceptable tradeoff of archive coverage and working response times.

3.2.2.2 Division of Current Data

Division of current data was necessary because sequential search response times were predicted to range between 15 and 20 minutes (based on an expected 16,000 to 24,000 records in the "current" data base, and extrapolating the 20,000-record median with the predicted effective response time of 45 to 60 seconds per thousand records). The prospect of each user being able to complete only 3 or 4 searches against "current" data in an hour was deemed unacceptable for day-to-day access.

The division of ACMS current data was based on the same functional data component that was used for dividing archives data—the date closed. Current data, however, was divided not on the basis of *when* a particular item of correspondence was closed, but *whether* it was closed at all. This attribute produced a data division that combined small size and high usage, and offered users a high degree of consistency in anticipating and understanding the data divisions.

The open records were estimated to be a comparatively small subset of current data—probably 300 to 600 records. Disproportionately, the volume of transactions against open records was estimated to represent a substantial majority—probably 70 to 80 percent—of total update and retrieval transactions. (It should be noted that there remains a substantial number of updates against closed records, since the terms "open" and "closed" apply only to the progress of correspondence responses and not to data base activity. Some ACMS records are also appended directly as "closed" data.)

The mechanism for providing access to current data was to establish two separate INGRES table pairs (including both the master and keyword tables): one pair for closed records ("cmaster" and "ckeyword"), and one pair for open records ("omaster" and "okeyword"). The application would employ separate commands for performing searches against the closed or open tables, and a third command for searching both table pairs.

The tests that were used to select an INGRES data base structure (see Section 3.4, below) included tests against a 371-record table. Again, the tests were conducted under ideal conditions to compare data base structures, rather than predict loaded-system response times, but under those ideal conditions the sequential search against the 371-record table ranged from 9 to 10 seconds. Using unloaded-system to loaded-system experience, non-key access against the open table could be expected within 30 seconds—well within acceptable limits for that type of search. The size of the closed table, however, was not reduced substantially by removal of open records (accordingly, the predicted response times were not improved for closed data), but the resultant decrease in searches against that table diminished the expected occurrence and impact of 20 minute sequential searches.

To minimize the need for non-key searches, it was decided to define virtually every field subject to regular searching as a secondary key. Search patterns could not be measured on the existing system, but user-supplied estimates were used to identify 17 secondary keys. The keyword descriptor in the keyword table was also defined as a secondary key.

3.2.3 Other Alternatives Considered

Alternatives that were considered but rejected included different strategies for dividing current data, and approaches to improve the speed of the basic application development environment. Each of these alternatives is discussed briefly.

Different strategies for dividing current data were considered. Each alternative tried to define a comparatively small set of current data that represented the highest percentage of update and retrieval activity.

One approach would be to define a set of records that included all open records and all closed records that had been closed in the last 30 days. This alternative would substantially increase application complexity, and would increase the difficulty of predicting where a given record might be located. The latter result, in particular, would effectively eliminate the advantage of having a small file that can be searched rapidly—since users who do not have a good idea where a record is located would have to search both files.

A second alternative for dividing current data would be to group all records that had some form of data base activity (including append) in the last 30 days. This alternative might successfully define a set of records with the highest percentage of future activity (although it might not), but it completely eliminates the advantage of the exercise. Again, users would have very little chance of predicting where a given record is stored and the resulting usage pattern would likely be to search both parts of the data base—thereby eliminating the advantage of having a small file that can be searched rapidly.

The division of current data that *was* implemented was not accomplished without a cost in application complexity: all transfers between open and closed files must be done interactively, as the user changes the status from open to closed, or vice versa. It was difficult using EQUEL to track the progress of all steps in the combined append/delete operation, and to "back out" the effects of a partially completed transaction if a problem was encountered during update.

Another set of alternatives that was considered for resolving size-dependent performance problems dealt not with the volume of data, but with improving the speed of the application environment.

Several hardware/operating system-level alternatives for increasing data throughput were briefly investigated. These included dedicating a separate VAX host to the application; tuning the system parameters of one or more VAX cluster hosts to INGRES; increasing the priority of underlying INGRES processes; and installing a RAM-based disk emulator (the data base would be stored entirely in Random Access Memory (RAM), protected by an uninterruptible power supply, and backed up regularly; data throughput would be limited by the speed of the VAX bus rather than by hard disk data transfer rates). These alternatives were rejected because: a) they were considered beyond the scope of the project, and b) achieved response times were expected to be within acceptable ranges.

A software-based alternative that would modify the basic performance of the application environment was also considered. The suggested technique was to write a two-part custom "background processor" that handles all interaction between user programs and INGRES.

The first part of the background processor is a custom back end. User programs compose transactions to be applied to the INGRES data base (updates, deletes and appends); transaction requests are sent to the back end; the back end is interruptible for purposes of receiving and queuing transaction requests; the user program is free to compose additional transactions as soon as the transaction request has been accepted by the back end; and when not handling interrupts, the back end submits the INGRES transactions.

The second part of the background processor is a custom front end. The background processor starts each day by loading data base contents into memory—e.g., FORTRAN arrays; the arrays are made accessible to user programs; user programs conduct searches against the arrays instead of against INGRES data bases; and the arrays are updated by the back end.

The back end approach could be well suited to a transaction-intensive application where update transactions are very lengthy and there is a desire to free data entry operators from the idle time waiting for transactions to complete. The custom front end could help to provide very rapid access to a fairly small number of records (limited by VAX memory: 2,000 records would require 3.5 Megabytes of dedicated memory), but the complexity of writing a FORTRAN-based DBMS for access to FORTRAN arrays (INGRES does not support access to program arrays) could be quite cumbersome. In both cases, error handling and concurrency would be delayed substantially. These conditions were not well suited to the ACMS application and the background processor approach was not considered applicable to the ACMS size-related performance problems.

3.3 CHOICE OF AN INGRES DEVELOPMENT TOOL

INGRES' Application-By-Form (ABF) offers a framework for building a menu-driven application that invokes developed modules at user direction. There are several different languages, preprocessors, and other application development tools that can be used to develop the modules.

The actual mix of application development tools chosen was a function of many different factors, including maintainability, flexibility, features, user interface, and consistency. Performance was one of the factors considered in the selection process—and an important factor—but it was not determinative.

Very early in the system design process, it became useful to test comparative performance of two INGRES development tools: Query-By-Form (QBF) and FORTRAN-based Embedded Query Language (EQUEL). The results of those tests are presented in this section.

3.3.1 Selection Process and Test Methodology

In selecting application development tools, a concerted effort was made to use standard INGRES features—particularly features that are recommended in INGRES documentation. This was a strategy expressly developed to maximize consistency, maintainability, and portability of the application. These considerations also strongly discouraged use of non-INGRES development tools (such as programming languages and form-creation systems), non-INGRES system features (such as VMS files, VAX-specific FORTRAN library routines, or VMS system calls), or undocumented INGRES features (such as "tids"—tuple ID numbers).

What remained was to decide on the facilities that would be used to develop modules to be called in the ABF application. QBF represents INGRES' most automated development tool and can be used to rapidly develop most of the basic DBMS transaction handling and command structures (such as search, update, append, and delete). INGRES' Operations Specification Language (OSL) and EQUEL are programming languages that offer greater flexibility, but they require the developer to custom program all commands and operations. EQUEL was selected over OSL as a programming tool—based on programmability and feature limitations in OSL—and the FORTRAN-based version of EQUEL was selected over other versions (such as BASIC, COBOL, and C) on the basis of features, available user interface, ease of maintenance, and ease of modification.

In comparing EQUEL and QBF, it appeared that QBF had some severe operational restrictions. Rather than

expend considerable resources to identify the limits of QBF programmability, a series of performance tests was developed to determine whether QBF would be disqualified on performance grounds—without regard to programmability. With these limited objectives, the test did not warrant sophisticated control conditions or extensive testing. The tests are described below.

Nine query scripts were developed to operate against three test correspondence table pairs (see Section 3.3.2, below). The queries were run during normal business hours, when the VAX was being used for other purposes; there were usually between 10 and 15 other users; no other users were accessing the test data base or any part of INGRES software; monitoring of system process activities indicated that no large jobs were run during the tests. Queries that completed in under 5 minutes were repeated 10 times, queries that took between 5 and 10 minutes were repeated 5 times, and queries that took more than 10 minutes to complete were repeated only 3 three times. The results from repeated tests showed very little variability, and that variability decreased as the length of response increased. The pattern of results suggests that the decreasing variability reflected a flatter distribution of conflicting VAX processes. Queries that failed to complete within twenty minutes were terminated. Performance times were measured by hand (QBF does not have a facility that would permit system-based time tracking). Reported results are averages of recorded times.

Since we were not trying to test the performance impact of QBF's output and format limitations (one premise of the test was that mechanisms might exist to eliminate such limits), the EQUEL programs were constructed to emulate QBF output—displaying retrieved records on the user screen. The most significant impact of this choice was that comparative performance could be measured by recording the appearance of the first character of the first qualifying record. Since there were no perceptible delays of data transmission after that first character appeared, we concluded that measuring beyond that point would unnecessarily introduce data transmission variation into the results.

Table 1. Development Tool (QBF/EQUEL) Test Queries

Test Number	Field Size	Operator	Wildcards	53-Record Table Pair Count	53-Record Table Pair % of Total	371-Record Table Pair Count	371-Record Table Pair % of Total	20K-Record Table Pair Count	20K-Record Table Pair % of Total
Primary Key—Master Table

NOTES:

- Results reflect time to display first retrieved record. Time to display subsequent records are not shown, and did not vary significantly between QBF and EQUEL.
- Asterisk (*) indicates that this query caused the session to be terminated, disk allocation to be exceeded, and the data base to need restoration before further use.

The recorded times, therefore, represent only *part* of the actual retrieval time and cannot be compared to complete-retrieval times. In particular, they *cannot* be compared to the complete-retrieval times reported in Section 3.4.

3.3.2 Test Queries and Test Results

Queries were conducted against three separate pairs of related tables. Logical records were defined as master records uniquely identified with a 10-character alpha-numeric primary key, and repeated occurrences (no more than 10) of detail records related to the master by the same primary key. Master records contained approximately 1700 characters each; detail, or "keyword" records contained approximately 30 characters. The three table pairs are described below:

Table Description	Table Names	Number of Rows
53-record table pair	hmaster	53
	hkeyword	104
371-record table pair	tmaster	371
	tkeyword	707
20K-record table pair	cmaster	20,085
	ckeyword	38,288

The 9 sample queries used in the test are shown in Table 1. The test queries are grouped into three major categories:

- o primary key searches against the master table
- o non-key field searches against the master table
- o non-key field searches against the keyword table

Each test query is numbered. The table shows—for each "test number"—the length of the searched field and the query operator used to identify qualifying records. It also shows whether the data specified as criteria was an exact value, or a partial value used with the INGRES asterisk (*) wildcard character. When a wildcard was used, its relative position to the partial value is also shown. The table also shows a count of how many records from each table met the qualifying criteria, and what that count represents—expressed as a percentage of the searched table.

The test results, presented in Table 2, show the measured times to retrieve the first character of the first retrieved record, using the application development tool shown against each of the three table pairs. The "test numbers" correspond to the "test numbers" in Table 1. All times are displayed in minutes:seconds.

The results demonstrate rather conclusively that QBF, and the QBF-enforced relational join, could not be effectively used with the volumes of data required in the ACMS data base. EQUEL was therefore chosen for developing correspondence management modules.

3.4 CHOICE OF AN INGRES DATA BASE STRUCTURE

INGRES offers four basic data base structures; each structure is available in an alternate compressed form (the compressed data base structures employ algorithms to detect and remove frequently repeated characters, such as blanks, thereby reducing the amount of disk storage required to store the data):

Uncompressed	Compressed
HEAP	CHEAP
HASH	CHASH
BTREE	CBTREE
ISAM	CISAM

A discussion of how these structures operate is contained in INGRES documentation and training.[9] But the discussed characteristics—such as internal operation, dynamic index revision, and need for re-indexing—were subordinated to a single, measurable factor: performance. Under some circumstances these other factors might have considerable impact, but late-night processing availability at the VAX facility permits daily creation of all indices, and the aspects of internal operation were viewed as incidental if they did not translate into measurable performance advantages.

Tests were developed to compare performance of the available data base structures. The results of those tests are presented in this section.

3.4.1 Selection Process and Test Methodology

The purpose of the test was to compare performance of different INGRES data base structures against tables that would approximate the size and nature of the ACMS data.

In selecting which structures to test, a pre-screening process was used to reduce the number of tested structures to three, and the number of target table pairs to two.

It was not difficult to remove HEAP (and the compressed version, CHEAP) from consideration: HEAP is a non-indexed structure and promised an unacceptably long sequential search even when the uniquely-assigned control number was specified. The choice of testing compressed versions of the remaining structures—or uncompressed—was a difficult one. It was very likely that disk storage constraints in the production system would require use of compressed structures. However, we concluded that the algorithms for compressing and uncompressing were likely to be identical in each of the data base structures, and we did not want to add that factor into a test of comparative structure performance. This consideration was strengthened by the fact that we did not yet have reliable estimates of how much blank space would be in the data, and therefore did not yet know whether compression would be a large or small factor. Based on these considerations, the adopted strategy was to test the three indexed data structures in their uncompressed versions. The tests would be repeated using the compressed version of the apparent winner, to gain a better understanding of the potential effect of compression.

Among the three table pairs available and developed for testing (See Section 3.3, above), the 53-record table pair was not used. The 20,085-record table pair approximated the size of the ACMS "closed" data set; the 371-record table pair approximated the size of the ACMS "open" data set; but the 53-record table pair was not meaningful for any group of ACMS correspondence data.

A series of 31 EQUEL-based data base transactions was developed (see Section 3.4.2, below). Since the most important purpose of the tests was to compare performance of the structures—and not to predict actual user response times—the transactions were run during off hours, after completion of all backup procedures or on weekends, but only when the VAX was being used by no other users, batch jobs or other processing. All transactions were run through completion. Reported results were "wall clock" times, measured by access to FORTRAN-library VAX system calls ("lib$init_timer" and "lib$show_timer") in order to avoid INGRES-driven contention by using INGRES to access system statistics.

---

[9] Relational Technology, Inc., INGRES Reference Manual, Version 4.0 VAX/VMS, Alameda, CA, (1986).

3.4.2 Tests and Test Results

Transactions were conducted against two separate pairs of related tables. Logical records were defined as master records uniquely identified with a 10-character alphanumeric primary key, and repeated occurrences (no more than 10) of detail records related to the master by the same primary key. Master records contained approximately 1700 characters each; detail, or "keyword" records contained approximately 30 characters. The two table pairs are described below:

Table Description	Table Names	Number of Rows
371-record table pair	tmaster	371
	tkeyword	707
20K-record table pair	cmaster	20,085
	ckeyword	38,288

Each table pair was "modified" (an INGRES operation) to the tested data base structure on "control_no"—the primary key; a secondary key was defined for each master table, on the "act_office" field (used in the test transactions), and a secondary key was defined for each keyword table, on the "keyword" field (also used in the test transactions). All fields used in test queries were "optimized" for each table, a "sysmod" was run, and the tests were started immediately thereafter (the quoted functions are INGRES operations, recommended in INGRES documentation for maximizing performance). No operations were permitted to the data base between the start of the modify and the completion of the last test. The entire testing process lasted 5 to 10 hours. Interruptions were possible (occasionally unavoidable), and the tests were completed on another night or weekend.

The 31 sample transactions used in the test are shown in Table 3. The test transactions are grouped into five major categories:

- o primary key searches against the master table
- o non-key field searches against the master table
- o secondary key searches against the master table
- o secondary key searches against the keyword table
- o updates to the master table.

Table 3. Data Base Structure Test Transactions

Test Number	Operation	Field Size	Operator	Wild-cards	371-Record Table Pair Count	371-Record Table Pair % of Total	20K-Record Table Pair Count	20K-Record Table Pair % of Total
Primary Key—Master Table

22.	retrieve	20	>=	exact	84	12%	4540	12%
23.	retrieve	20	=	*part	77	11%	4160	11%
24.	retrieve	20	=	part*	77	11%	4160	11%
25.	retrieve	20	>	part*	7	1%	380	1%
26.	retrieve	20	>=	part*	84	12%	4540	12%
27.	retrieve	20	=	*part*	77	11%	4160	11%
Updates—Master Table								
28.	replace	1674	=	exact	1	<1%	1	<1%
29.	append	1674	=	exact	1	<1%	1	<1%
30.	delete	1674	=	exact	1	<1%	1	<1%
31.	replace	25	=	exact	1	<1%	1	<1%

Each test transaction is numbered. The table shows—for each "test number"—the operation performed the length of the affected field, and the query operator used to identify qualifying records. It also shows whether the data specified as criteria was an exact value, or a partial value used with the INGRES asterisk (*) wildcard character. When a wildcard was used, its relative position to the partial value is also shown. The table also shows a count of how many records from each table met the qualifying criteria, and what that count represents—expressed as a percentage of the searched table.

The test results are presented in two tables—Table 4 presents results against the smaller 371-record table, Table 5 presents results against the larger 20,085-record table pair. Both tables show the measured "wall-clock" times to complete the test transaction, when the table pairs were modified to the indicated data base structure. The "test numbers" correspond to the "test numbers" in Table 3. All times are displayed in minutes:seconds.

The results demonstrated that INGRES' BTREE data base structure produced the fastest retrieves against both ACMS master tables, particularly in sequential (non-key) searches against the large data set (approximately 4 minutes faster—33 percent—than any other structure). Update transactions in BTREE were not the fastest (ISAM-based updates against the large master table were approximately 2 seconds faster—25 percent), but since the performance "bottleneck" appeared to be sequential searches, retrieval response times were considered more important than updates.

For the keyword table, results did not indicate a clear choice: most results were within 10 percent of one another. Against the small keyword table, ISAM was fastest on six of eight tests. Against the large keyword table, ISAM produced the best results for the two longest tests but was slowest on all others. HASH was fastest on six of eight tests against the large keyword table. Again, since the significant bottleneck appeared to be in searching the large table pair, performance against the large keyword table was considered

Table 4. Data Base Structure Test Results—Small Data Set (seconds)

Test Number	INGRES Data Base Structures HASH	BTREE	ISAM
Primary Key—Master Table			
1.	.82	.99	.82

21.	1.89	1.81	1.77
22.	2.05	2.18	1.98
23.	2.11	2.98	1.79
24.	2.02	1.84	1.87
25.	1.92	1.88	1.75
26.	2.06	2.37	1.95
27.	2.17	3.41	1.79
Updates—Master Table			
28.	2.44	4.53	1.68
29.	4.28	4.31	3.96
30.	1.15	.76	.50
31.	1.81	2.01	1.35

the most important—in particular, test number 20, since it was expected that most searching in the ACMS keyword tables would be done by exact match. The decision to use HASH, therefore, was based on superiority in six of eight large table tests, more consistent performance throughout the tests, and on superiority in the exact match test.

It should be noted that the relatively poor performance of HASH in the tested queries is considered primarily due to the use of non-key fields (test numbers 3 through 11), and to the use of partial values and comparative operators (test numbers 2, 13 through 19, and 21 through 27).

A final set of tests was conducted after modifying the test tables to the compressed versions of the selected data base structures: CBTREE for the master tables and CHASH for the keyword tables. The test methodology was the same as that described above; the results are shown in Table 6. The results confirmed that compression would not detract from performance in this particular test data base, and could actually deliver a substantial performance improvement.

4. IMPLEMENTATION-LEVEL FACTORS

This section describes the performance problems that were reported in the operational ACMS, the implementation-level factors that were determined to have a significant impact on performance, and the specific techniques and modifications that combined to resolve the performance problems.

Performance of the ACMS in the first few weeks of operation was marred by extreme line noise, severely interfering with data entry and retrieval. Response times were reported by users as being from 1 to 5 minutes—regularly exceeding 10 minutes, and occasionally in excess of one or more hours.

Several potential problem areas were identified, and simultaneous efforts were initiated to analyze and resolve them. Because of the severity of the problems, incremental solutions offering significant performance improvements were implemented immediately, and the chronology of implementation-level performance tuning was thoroughly intermingled.

Table 5. Data Base Structure Test Results—Large Data Set (minutes:seconds)

29.	8.75	4.88	4.61
30.	8.81	3.31	2.98
31.	13.10	1.73	1.42

Since the chronology and specific intermix of performance tuning implementation is only occasionally germane to the purpose of this report, this section will focus on the substance of the performance tuning factors and solutions, rather than on the sequence of events. The discussions of implementation-level factors are grouped into three functional areas:

- o Monitoring Operations and Performance
- o Application Environment Factors
- o Selection of Secondary Keys

All of the performance problems encountered after implementation were resolved through the performance tuning described in this section, and response times for most operations were lowered to within the 10- to 20-second objective defined at the beginning of the project. Observations and "lessons learned" from these performance tuning activities are summarized in Section 5.

4.1 MONITORING PERFORMANCE AND OPERATIONS

As problems were reported by users and incremental solutions were implemented, there needed to be a consistent mechanism for tracking the operation of the application and the effect of changes. The need for an operations and performance monitor also developed from some distinct advantages that could be realized in performance tuning in an operational rather than development environment. Specifically, the existence of live data and ongoing transactions offered valuable information about the ACMS data, data access and usage patterns, and actual (versus emulated or predicted) application performance.

INGRES does not offer a facility for tracking operations and performance, nor recommends a third-party monitor that would identify discrete transactions and report response times, CPU and disk usage, or other application-specific data. The solution was to develop a custom monitor by inserting measurement code into EQUEL-based application modules—which would append data reflecting operations and performance into INGRES-defined monitor tables. The monitor tables could then be reviewed as needed, providing a historical data base of monitor data, without significantly interfering with on-going ACMS operations.

Table 6. Data Base Structure Test Results—Compression
(minutes:seconds)

29.	4.31	3.95	4.88	4.51
30.	.76	.75	3.31	3.21
31.	2.01	1.49	1.73	1.84

As with the other post-implementation performance factors, the need for a performance monitor was addressed simultaneously with other factors and the facility was developed and implemented incrementally. There was incomplete information on what data was needed; the operations portion of the monitor was used in an application debugging process (which is not described in this paper); and the nature of required operations and performance data changed as different solutions were investigated. As the monitor was being developed, every effort was made to retain consistency of collected data—to permit meaningful comparison of data collected over time. However, some measurement techniques had to be changed as inherent biases or inaccuracies were discovered. The final version of the monitor was changed to consolidate all the partially implemented monitor components into a single facility that produced consistent, accurate, complete results, with maximum efficiency and flexibility.

The final version of the performance and operations monitor appends a single record to an INGRES-defined "monitor" table for each ACMS correspondence transaction. Cumulative system values are captured at the beginning and end of each transaction, and the record is appended with key data related to the transaction (including the difference between "start" and "end" values) and the transaction's effect. Data captured includes:

- user—INGRES "username" indicating VAX USERID
- date—INGRES "_date" including time of day
- module—name of EQUEL program in use
- operation—nature of ACMS operation
- table_pair—affected INGRES table pair
- effect—such as: success, failure or delayed
- cpu—INGRES "_cpu_ms" CPU seconds
- elapsed—INGRES "_bintim" wall clock time
- direct_io—INGRES "_dio_cnt" direct disk I/O count
- m_control_no—correspondence control number
- m_where_cl—where clause used in transaction (part)
- m_rcount—INGRES "rowcount" number of rows affected
- m_ingerr—INGRES "errorno" transaction return code

In addition, three alpha fields (named "a," "b," and "c") and three numeric fields ("x," "y," and "z") were defined, to permit ad hoc capture of transaction-related data without modifying the monitor.

Clearly, some portions of the monitor data (such as module, operation, and control_no) contained essential identifying information. Some portions of the monitor, however, proved to be more valuable than originally expected. In particular: the user field was valuable in tracking operational anomalies; the effect field permitted identification of transactions that had failed or been delayed through user action; and the elapsed field produced the most meaningful comparative performance statistic. The cpu and direct_io fields were used occasionally to isolate communications and secondary key problems, but were not especially useful in actual performance tracking.

The measurement of elapsed "wall clock" times proved to be the most difficult: INGRES' "_et_sec" produced dramatically unreliable results. The method implemented was to note the start and end times, expressed as the number of seconds since January 1, 1970 (INGRES "_bintim(0)" function), and capturing the difference. Elapsed times measured using this technique and actual times measured at user terminals were consistently within 2 or 3 seconds of one another.

Captured performance data was then available for any query that might be desired, but for purposes of regular operations and performance review the data was summarized into two key reports: response time distribution, and query field-usage.

To produce the response time distribution report used in daily review of transaction response times, the wall clock results from the monitor table were summarized and appended into a second INGRES-defined table ("freq") in which response times were broken down into the following distributions:

- 1st-level distribution (ACMS operation)
  - append
  - move
  - replace
  - retrieve
- 2nd-level distribution (response time intervals[10])
  - 0 to 5 seconds
  - 5 to 10 seconds

Figure 3. Sample Response Time Distribution Report

"move" operation is specific to the ACMS application. Specifically, moves occur when the status of a correspondence item is changed from open to closed (or from closed to open) and the logical record is moved from the open table pair to the closed table pair (or vice versa). A recorded "move" operation, therefore, includes both an addition to one table pair and a deletion from the other.[11]

The distribution scale used in the response time distribution report is not an arithmetic progression—the size of each interval increases as the response times increase. These response time intervals were tailored to the particular performance history of this application and to the target performance objectives. Under other circumstances, an appropriate distribution scale could be very different.

A second key part of the monitor was the query field-usage report. This report, an example of which is presented in Figure 4, produced a cumulative record of the fields used in user-defined queries, together with the number of times each field was specified. This data provided usage pattern information that was very helpful in selecting secondary key fields (see Section 4.3, below). One of the system costs of running the field-usage part of the monitor is that a separate "monitor" record was appended for every field used in a query. Accordingly, a complex query could impose an overhead of 15 to 20 INGRES appends before the query was actually started.

Figure 4. Sample Query Field-Usage Report

4.2 APPLICATION ENVIRONMENT FACTORS

The operations and development environment of the ACMS application had a severe impact on performance, but these factors were generally outside the scope of performance tuning. They are reported here because of their significant potential impact on performance. The factors include: communications, ALL-IN-1, and software releases.

4.2.1 Communications Environment

As shown in Figure 1 (see Section 2.1, above), CFU users were connected to the VAX cluster through dial-up asynchronous modems, then connected through a switch to a user-selectable VAX cluster host ("node"). Line noise experienced by users was sporadic, and occasionally quite severe: in some cases, INGRES commands could not be executed because line noise would not permit entry of discrete commands.

Numerous efforts were undertaken to resolve the line noise problems—such as changing user modems, changing VAX modems, examining telephone lines, and direct connection to the VAX (bypassing the cluster switch). The noise abated somewhat, but persisted on occasion and was eventually found to be causing several operational anomalies: the user's terminal would have all the function key definitions changed; the telephone connection would be dropped; the modem would reset; data would be lost; and the screen would freeze, go blank, or change to a graphics character set. Examination of these problems—particularly the case where the screen would apparently freeze—eventually revealed that several reported "performance" problems were actually caused by communications problems.

Since the communications environment was not in our scope of control, we do not have statistics on the impact of specific changes. However, by the time the communications problems were resolved, performance times had been reduced substantially: most appends completed within 20 to 30 seconds; most non-primary key retrieves completed within 10 to 40 seconds.

Not all of the noted improvement was attributable to communications—several other environmental factors had changed and secondary keys had been tailored. But the pattern of dramatic performance problems decreased steadily as communications problems were incrementally resolved, and the patterns continued to decrease until the problems were only sporadic and readily traceable to individual transactions. Also, the nature of secondary key tailoring strongly suggests that communications had been responsible for: the 1-to-10 minute response times on key-field searches; on virtually any poor retrieval performance when the primary key (control number) was supplied; and on any responses beyond 10 minutes.

4.2.2 ALL-IN-1 Environment

As also shown in Figure 1 (see Section 2.1, above), the ACMS is invoked from within DEC's ALL-IN-1 Office Automation system, and operates as a sub-process under ALL-IN-1. The impact of operating the ACMS as a sub-process is not known.

The VMS operating system is specifically designed to offer the same processing environment—in terms of both performance and operability—for any VMS process or sub-process. However, that goal is not always achieved. ALL-IN-1, in particular, changes the sub-processing environment in a number of ways that we observed over the course of the project, and presumably in other ways that we did not observe. Also, the combination of INGRES and ALL-IN-1 produced some unpredictable results. The question was raised as to whether the combination of INGRES and ALL-IN-1 might be having a significant impact on performance.

[11] It should be noted that the usual DBMS "delete" operation is not shown because CFU users do not ordinarily delete correspondence records from the ACMS data base

The advantage of maintaining a consistent user interface for VAX operations was considered by VAX systems personnel to be very strong. Accordingly, no attempt to temporarily investigate the potential impact of removing the ACMS from ALL-IN-1 was made. Under other circumstances, however, this environmental factor might be further investigated.

4.2.3 Software Releases

A number of new software releases were implemented during the application development and performance tuning periods. This included two new releases of INGRES, a major release of ALL-IN-1, and an upgrade to VMS operating system. Performance was not affected by the non-INGRES upgrades; the INGRES upgrade from 3.0 to 4.0 occurred before reliable performance test procedures could report significant performance changes; and the upgrade from INGRES 4.0 to 5.0 is estimated to have produced a 10 to 15 percent performance improvement. Each of these upgrades and results is described below.

Following implementation of the ACMS, VAX VMS was upgraded from version 4.4 to version 4.5. At the same time, ALL-IN-1 was upgraded from version 2.0 to 2.1. The application had to be recompiled, but there was no significant impact on performance.

INGRES was upgraded from version 3.0 to 4.0 towards the end of application development activities. As mentioned, this was before test procedures had been developed that would reliably report performance changes. Operationally, however, no significant improvements were observed.

INGRES was upgraded from version 4.0 to 5.0 about a month after implementation. The INGRES Release Notes Version 5.0/02 (Relational Technology, Inc., 1986) states that "5.0 is primarily a performance release of 4.0," offering "significant performance improvements in ... queries involving btree tables." The installation immediately followed secondary key tailoring, and preceded resolution of communications problems.

For the few days of performance statistics that were collected surrounding the INGRES 5.0 installation but unaffected by other significant implementation-level changes, there was no reliably demonstrable performance improvement, but it seems quite likely that a performance improvement did occur. Specifically, average retrieval times increased from 13.714 seconds to 19.744 seconds and average append times decreased from 48.315 seconds to 33.500 seconds. However, significant communications-related problems were still occurring that could have distorted average results. When times under 100 seconds are removed from the results, the retrieves under version 5.0 show a 27.53 percent improvement (from 10.652 down to 7.720) and appends show a 19.85 percent improvement (from 30.633 down to 24.553). These improvements, however, are likely to be overstated. Actual performance reflects varying loads on the VAX cluster and the three days measured after the new release was installed were the three days before the Thanksgiving holiday: overall VAX usage was noticeably lower. Our estimate is that the new release of INGRES actually improved performance 10 to 15 percent.

4.3 SELECTION OF SECONDARY KEYS

The selection of secondary keys was the single most significant implementation-level factor that was within proper control of the performance tuning project team. Secondary keys are essential for rapid access to a large data base—thereby reducing the need for searching the data sequentially. But the existence of secondary keys causes response times for appends and updates to increase substantially—as indices are updated. The most important factor in secondary key tuning is to find the particular set of secondary keys that produce the optimal mix of retrieval and update performance. In the ACMS, usage statistics identified six fields that represented 98 percent of all searches. Secondary keys were defined for each such field and the update response times were able to be brought into an acceptable range (see Section 4.4.1, below).

The initial set of secondary keys defined in the ACMS data base included 17 fields. Response times for appends and updates were verified to be running as long as 5 to 10 minutes—occasionally as long as 20 minutes—without the effect of communications problems. Disk I/O statistics indicated the presence of extraordinarily high disk activity, suggesting that the number of secondary keys was responsible.

Secondary keys were then eliminated from the ACMS file structures. The effect on performance was a dramatic improvement of response times for appends and updates, and a dramatic degradation of response times on all queries (except when the primary key was specified). The result was that users concentrated their activities on appends and updates, and use of the system for retrieval and reference purposes was limited almost exclusively to instances in which the control number was already known. While this process successfully improved reported response times (appends and updates were completed in 20 to 30 seconds), the situation would not be acceptable on a long term basis.

The field-usage portion of the custom monitor (see Section 4.1, above) captured the information essential to meaningful secondary key tailoring: which fields were being used in user queries?

Initially, secondary keys were defined on the basis of user interviews and claimed requirements. As the monitor's field-usage statistics developed a significant history, six secondary keys were identified. The accumulated query field-usage report presented in Figure 5 shows that the six fields—together with the primary key—represented more than 93 percent of all user queries, and that all of the six fields were used substantially more often (generally more than ten times as often) than the next most frequently used fields.[12]

As additional fields were added (one at a time), an attempt was made to judge the performance impact of each change. However, differences in daily work loads —by CFU users, by other users on the VAX, and by other system developers—contributed to a wide variance of performance results. There was no single secondary key that improved response times by an amount that could be reliably measured from actual-use performance data, but the cumulative effect of the secondary keys was both clear and dramatic.

When all six secondary keys were implemented (but before all the communications problems were resolved) most appends and updates were completing in under 60 seconds. 98 percent of all queries were being conducted with the use of secondary keys. Queries that were fairly straightforward, single-field specifications were completing within 20 to 30 seconds; queries that used complex combinations of wildcards, comparative operators (greater than or less than), and master-keyword joins were taking 1 to 5 minutes; and the 2 percent of non-

[12] It should be noted, however, that incremental implementation of secondary keys must be regarded as having introduced a possible bias towards keys that were defined earliest in the process: user experience could have lead to greater usage of those fields, since they were producing faster results. But because of the wide disparity of usage patterns, it appeared that the effect of such bias was slight and that the selection of secondary keys reflected actual usage requirements.

Figure 5. Query Field-Usage Report—Two Months Cumulative Data

key searches often required 5 to 15 minutes. When the communications problems were resolved, these responses settled into the following predictable ranges:

- o appends: 15 to 20 seconds
- o moves: 15 to 25 seconds
- o replaces: 20 to 30 seconds
- o retrieves: 5 to 15 seconds

These results do not include the 1-to-3 second response times for retrieval when the control number was specified, nor the occasional complex-query search that ranged from 30 to 90 seconds, nor the occasional sequential search that required 5 to 10 minutes.

These times were within the 10- to 20-second response time targets established at the beginning of the project. Additional tuning, specific to programming in INGRES and not within the scope of this paper, further improved performance of the replace operation. Following the INGRES-specific tuning, the average response time for the replace operation was under 2 seconds.

5. SUMMARY

The principal objective of performance tuning the ACMS application was to bring response times to the interactive level described during the initial stages of system development: "pre-defined system operations must be accomplished within 10 to 20 seconds." This objective was achieved.

The performance tuning process produced several findings that are valid only for the particular circumstances of the ACMS application, running in the then-current hardware and software environment of the agency's VAX cluster, based on the user requirements, data usage patterns, and operational preferences of the CFU personnel. However, many of these findings may be relevant to applications with similar characteristics, such as (depending on the nature of the specific problem encountered): similar correspondence management functional requirements, VAX or VAX-cluster operating environments, an INGRES development environment, or a development environment using a relational data base.

This section describes findings from the ACMS performance tuning efforts, and describes the general conclusions that might be drawn from these findings.

5.1 FINDINGS FROM ACMS PERFORMANCE TUNING

The most significant performance improvements in the ACMS were attributable to the following factors:

- o Abandoning the "relational" data base model was essential. Relational joins had to be virtually eliminated, even if it meant modifying the logical record structure to violate the first-normal-form principle of the traditional relational model (to reduce the number of related tables). The process of only retrieving primary keys from user-specified queries, then using primary key searches to collect and accumulate logical records (the split-retrieve approach) was also important in reducing the use of relational joins.

- o Division of data was also essential. Under the existing configuration of hardware and software, the application simply could not produce satisfactory response times against the entire 50,000-record data base.

- o The selection of secondary keys produced a significant performance improvement. In the ACMS application, some number of secondary keys had to be used to gain rapid access to the volume of on-line data, but a high number (17) of secondary keys degraded performance too much. Measurement of post-implementation usage provided the most reliable information for selecting the final set of six secondary keys.

- The operations and development environment also had a dramatic impact on performance. For the ACMS application, these factors included: communications, selection of the most efficient development tools and structures, and effective use of available DBMS programming techniques.

- Implementation of a performance monitor was an essential component to the performance tuning process. In this case, the monitor had to be developed and installed in the INGRES application on a custom-programming basis.

The key finding that pertains to performance tuning in a relational environment, is that *for certain applications* the relational model (and the relational join, in particular) contains an inherent characteristic that *prevents* reasonable performance—irrespective of the hardware, the DBMS, the operating system, or any other factor affecting implementation of the relational model software. Specifically, the multiplicative effect of the relational join produces a situation in which the number of records retrieved in order to accumulate a single logical record is extraordinarily large. In the example application, there were 7 detail records in each of 7 detail tables; the resulting join produced a retrieve that had to go through 823,543 records. With approximately 1750 characters per record, the total amount of data that had to be processed was 1.44 gigabytes—*per logical record*. Adherence to strict relational principles, and to strict normalization techniques, ensures a high number of related tables in even a moderately complex application. If the user requirements dictate access to all related data—enforcing the concept of the logical record—then the result will be a system in which performance is measured in days, rather than seconds.

5.2 CONCLUSIONS

Although the actual findings presented in this report apply only to the individual circumstances of the ACMS, the nature of the problems identified and resolved suggest that the following conclusions might apply to data base application performance tuning in general:

- The relational data base model is often regarded as capable of emulating virtually any data base structure. However, the performance implications of emulating other structures—especially if several relational joins are required—suggest that while emulation may be possible, it might not be practical, even with a very small data base (e.g., 53 records). The key to this performance limitation is de-normalization during relational joins: de-normalization creates a multiplicative effect of related detail records stored in related tables, which can be devastating to performance.

- Performance tuning requires concerted effort in evaluating and choosing data set characteristics: division of data into discrete tables; DBMS "structure" of each table; and secondary keys. The solution to each of these problems may require exploration of a wide range of alternatives, thorough pre-implementation testing, and a willingness to make dramatic changes even after the system is operational, but each has a significant impact on performance—especially when the size of the data base is large.

- A thorough familiarity with the features and application development tools of the selected DBMS is essential during the performance tuning process. This does not mean that all possible features must be used—in fact, many offer only marginal performance improvements or may introduce unwarranted complexity into the application. But understanding the DBMS features and tools is important in identifying possible alternatives, and in evaluating their potential performance-related and design-related impact.

- When concerted post-implementation performance tuning is required, a good operations and performance monitor is especially important, even if it means that the monitor must be custom-coded. Monitoring an operational system can also provide information that is extremely valuable in performance tuning—information that cannot be determined through user interviews or simulation.

A final factor that was extant throughout the ACMS performance tuning process, but which was not a deliberately considered approach with alternatives and analysis (and therefore not subject to analysis in this report), was a positive working relationship between the CFU users and the performance tuning project team. Without this relationship, without the communications, without the openness, candor and hard work that characterized the relationship, the performance tuning effort would have suffered dramatically. Coordination of tuning efforts with the users and good communications was essential to being able to tune an operational system, and to achieving user satisfaction.

EMPIRICAL MODELS OF DASD RESPONSE TIME

J. B. Major
IBM Canada Ltd.
Montreal, Quebec

ABSTRACT

Several models of system-wide average DASD response time are studied. Factors considered are: utilization of the average and of the busiest actuator as well as the time-varying nature of these, that of the average DASD controller and the system-wide average DASD service time. The latter is, in turn, modeled with respect to actuator types and the presence or absence of cache controllers. DASD response time is represented as a family of piece-wise linear lines for specific levels of DASD controller utilization. The results are used to stipulate DASD configurations that would give specified response times for desired levels of DASD traffic. Model validation is reported for various groupings of the more than 100 days' data that were contributed by more than 20 installations in a wide range of industries of mostly MVS/XA systems, many with shared DASD. Interpretation in terms of some commonly used queueing models is discussed.

INTRODUCTION

In the course of his work with several clients the author has collected hundreds of hours' worth of DASD performance data. Attempts were made to relate I/O response times (RT) as reported to workload and I/O device related information, data that could be obtained from the Direct Access Device Activity report of the Resource Measurement Facility (RMF) of MVS/SP2. It is noted that actual RT may exceed the reported level due to software queueing. Resource usage and I/O response time relationships included considerations for different I/O device types (IBM 3380 type disks, standard, or D and E models, IBM 3350 type disks and IBM 3880 or equivalent storage controllers with or without cache).

Response time models of these types of environments have been offered before (cf. <1>, <2>, <3> and <4>, as examples). All of the models are based on probabilistic and queueing considerations and necessitate unverifiable assumptions about the nature of the I/O traffic. Simulation might be offered as a validation tool. Unfortunately, the simulation runs are burdened by essentially equivalent and unverifiable assumptions about the I/O traffic with the reassuring result that the mathematical formula and the discrete event simulation both predict comparable response times with remarkable accuracy as compared to one another. Accuracy with respect to the real world is another matter.

The work reported here gives I/O response time predictions usually within 6% of the observed figures when the observed I/O service time (ST) is considered to be given. In fact, ST itself has to be predicted. The proposed prediction of ST is accurate usually within 7% of the measured results. Prediction errors of this size might be considered more than acceptable. However, when one considers the configuration implications of these errors, one might have another view. The point is discussed in the Section on PREDICTION ACCURACY.

The models proposed require estimates of system-wide DASD I/O rates (per second) during the planned period of operation (usually the prime shift). In addition, we need the system-wide average connect time (per I/O), as well as the expected SKEW of the I/O load. SKEW is defined as the maximum DASD actuator busy level divided by the average DASD actuator busy level over all the actuators of a configuration. This idea has been motivated by <5>. RMF reports the connect time by actuator and by Logical Control Unit (LCU). The system-wide average can be calculated from the LCU data. Finally, the fraction, FNCH of the non-cached DASD Control Units (CU) as well as the fraction, FNDE of the non-D-or-E 3380 actuators is required to complete the estimation of ST. One can view these fractions as configuration rules. No assumption is made about the ST distribution or about the I/O interarrival times.

Measurements of more than 20 systems over more than 100 shifts in a variety of industries validate the predictions.

This paper is a generalization of the author's study of a Law of Diminishing Returns (LDR, first stated in <6>, and refined in <7> with respect to the I/O traffic capacity of DASD actuators as seen in the Section on LDR PERSPECTIVE.

To facilitate reading, acronym definitions are given in FIGURE 11.

TRANSACTION RESPONSE TIME

DASD I/O response time is an important consideration in the process of configuration selection to the extent that it influences the response time of transactions from the point of view of the users of a host system. Naturally, the user's perception of response time is generated by several factors: communication time, software caused delays, and, last but not least, I/O servicing. The latter includes all the code execution and processor contention times that are associated with servicing a "typical" I/O as well as the response time of the I/O subsystem. Thus, transaction response time is composed of

a. communication delay
b. initial software delay (e.g. swap-in or attach)
c. software serialization or synchronization delay
d. several I/O servicing instances (DASD and CPU)

Of these, a. is a function of workstation attachment (on local or remote, and, possibly quite slow communication channels) and is not discussed any further here. Items b. and c. are software implementation dependent and are not discussed here beyond the remark that synchronization is usually an application code function (to ensure data integrity), serialization may be caused by application code or by application control software (CICS, IMS, others). In the latter case judicious choice of environment setup parameters can significantly reduce or altogether eliminate these delays. The remaining terms relate to the operation of the processor (that is analyzed in a companion paper <8>) and to the DASD subsystem, the subject of this paper. Tape and communication I/Os are omitted altogether.

This view assumes that I/O processing of a transaction is not overlapped with I/O processing or with CPU processing of the same transaction instance, and that all I/Os caused by a transaction add to its response time. That is not entirely the case. Swap-in or swap-out I/Os of TSO transactions are usually processed in parallel to the extent of swap dataset and I/O path multiplicity. Similarly, I/O buffer write-out may be more or less parallel in IMS systems at the time of transaction termination and might not add to the transaction response time at all. Thus, when an I/O response model consistently overestimates transaction response times at the host system level, and the model has been verified to be fairly accurate for some on-line systems, one can suspect overlaps of the above kind. Analysis of some controlled measurements of TSO environments that the author had access to indicated an I/O overlap factor of 1.05 - 1.18,

meaning that TSO response time would be overestimated by that factor without allowance for overlaps. This factor includes delays of the b. and c. type, that is the actual overlap effect is really greater than 5 - 18 %. Similar study of IMS measurements resulted in underestimation of the average response time by a factor of 1.0 - 1.2, where the high values correspond to high processor utilization levels, and in 1.0 - 1.5 for CICS environments. Again, large serialization adjustments correspond to high processor utilizations. Details are discussed in <8>.

As an example of DASD I/O processing impact on transaction response time, a TSO transaction mix might receive an average response time of 900 ms on an IBM 3090 processor (model 180 and up) half of which would be accounted for by the DASD subsystem's handling of the 20 or so I/Os that are normally associated with such transactions. These numbers assume locally attached workstations and 3380 D or E type DASD with no cache controllers.

MODEL REQUIREMENTS

A predictive model is a formula or procedure that incorporates one or more variables whose values can be measured or stipulated and one or more constants that apply to all the predictions. Calibration consists of choosing the constants that give a satisfactory (in accepted terms) prediction for the measured data space. Validation with additional data should not degrade or improve the quality of predictions. Further, the constants should not change with changes in software and hardware usage or with the application mix, unless the model is geared specifically to a subset of conditions that are assumed to be constant over time. In this latter case we could have several models, each with its own formula or procedure, and with its own constants. This paper limits the context to MVS/SP systems with most of the environments studied being of the SP2 (XA) type.

The model should be validated in terms of actual practical installation data that cover a broad range of systems and that span many hours of operation. It should produce reasonable configuration recommendations. A desirable feature of a response time prediction model is its interpretability in terms of queueing concepts.

The DASD I/O response time model that is proposed here meets the above requirements.

DASD I/O RESPONSE TIME FACTORS

The empirical DASD I/O response time model is based on information normally available from RMF DASD Activity reports (in MVS/XA). The relevant items are:

B	average actuator utilization (% busy)
X	maximum actuator utilization (% busy)
X/B	actuator utilization SKEW
LB	average DASD LCU utilization (% busy)
PB	average DASD I/O path utilization (% busy, PB = LB/2)
S	DASD SIO rate (per second)
RT	average DASD I/O response time (ms)
ST	average DASD I/O service time (ms)
CT	average DASD I/O connect time (ms)
D.TRF	DASD traffic (ms/s) D.TRF = S•ST
P.TRF	DASD path traffic (ms/s) P.TRF = S•CT
RT/ST	normalized DASD I/O response time
N	number of DASD actuators multiple of 4 when type is 3380
NCU	number of DASD control units a CU usually contains 2 DASD paths
NCUCH	number of DASD control units with cache
FNCH	fraction of non-cache control units FNCH = (NCU - NCUCH)/NCU
NADE	number of 3380-D or E type actuators
FNDE	(N - NADE)/N
NA50	number of 3350 type actuators
FR50	NA50/N

The last 7 items are not reported by RMF. They can be obtained from configuration diagrams or knowledge. Further, RMF does not report system-wide data for shared DASD. Report consolidation is necessary. A report consolidation and analysis program was developed by the author's colleague, L. Beauchemin and used extensively in the validation process.

DATA ANALYSIS AND RESPONSE TIME MODELS

Consider the measurement scatter illustrated on FIGURE 1. As seen, there is no clear relationship between the RT/ST ratio and the average actuator busy %, B, other than, by and large, higher levels of B correspond to higher levels of RT/ST. The different symbols used represent measurements with different levels of X/B. The highest ratios (x's) represent values around 10. Dots correspond to ratios around 7.5, triangles to 6 and squares to 4. With that in mind, a schematic shown on FIGURE 2 can be suggested as a model of the RT/ST versus B relationship. This family of piece-wise linear lines that correspond to given fixed SKEW levels forms the SKEW Model.

The above measurements represent shift averages taken over one to five shifts per point. Similar scatters are obtained when each point represents one shift only.

Three models of RT/ST are discussed now.

1. The SKEW Model

General algebraic formulation of the model is obtained from FIGURE 3 and is as follows.

Let SLOPE = (R2 - R1)/(B2 - B1). Then

$$RT/ST = \begin{cases} R1 & \text{when } B < B1 \\ R1 + (B - B1)\cdot SLOPE & \\ ? & \text{when } B > B1 + (R3 - R1)/SLOPE \end{cases} \quad (1)$$

R1, R2, R3 and B1 are model parameters that are estimated from data analysis. For a specific SKEW the SLOPE is found as

B2 = B.MAX/SKEW

B.MAX is also a model parameter that is estimated from data analysis. Based on the data analyzed, the following parameter values were chosen:

R1 = 1.2, R2 = 1.4, R3 = 1.6, B1 = 2, B.MAX = 60

These give RT/ST estimates with average absolute error of prediction of 6 % with error defined as

error = 100•(prediction - actual)/actual

In these terms, (1) applies when

1 < SKEW < 30, and 2 < B < 2•(60/SKEW - 1)

Otherwise, it is assumed that when B < 2 then RT/ST = 1.2, and when B > 2•(60/SKEW - 1), then RT/ST > 1.6 and is not very predictable. In terms of these parameter values, SLOPE = 1/(5•(60/SKEW - 2))

2. Path Loadings: the Calibrated SKEW Model.

RT/ST varies as the DASD path loadings vary. Generally, the busier the DASD paths, the higher is RT/ST. The SKEW Model's estimate of RT/ST can be corrected by stretching (multiplying) by the factor of

SF = 1 + 0.01•(PB - 8),

The corrected prediction is

(RT/ST)' = (RT/ST)•(1 + 0.01•(PB - 8))

Very low (< 8 %) path loadings correct the RT/ST estimate to a somewhat lower level, whereas high path loadings increase the estimate. Use of this correction factor has reduced the average absolute error of the prediction by somewhat more than 0.5 %.

In summary, the calibrated SKEW model is given by

$$RT/ST = \begin{cases} 1.2 \cdot SF & \text{when} \quad B < 2 \\ (1.2 + (B - 2) \cdot SLOPE) \cdot SF & \\ 1.6 \cdot SF + ? & \text{when} \quad B > 2 + 0.4/SLOPE \end{cases} \qquad (2)$$

$$SLOPE = 0.2/(60/SKEW - 2)$$

3. The Aggregate Server Model

If the average I/O response time of device n of an N device system is RTn for an average I/O rate (/second) of Sn then the system-wide average I/O response time RT is obtained from

$$RT = \sum_{n=1}^{N} (RTn \cdot Sn) / \sum_{n=1}^{N} (Sn)$$

Imagine a fictitious aggregate server (DASD actuator) that has the same average response time RT, and has an average utilization B that is the average utilization of the N DASD actuators. This fictitious aggregate server and its waiting line can be considered to form a single server queue. The Pollaczek-Khinchin (P-K) mean value formula (cf. <9>) could give a solution to this queue.

The emphasis is on capacity planning: represent the DASD system through a small set of parameters that yield equivalent response time to that of N DASD servers, each with its own queueing behavior without regard to the idiosynchrasies of specific actuator-dataset-access method combination effects.

Detailed models of DASD systems represent every actuator and its behavior through their various approximations. These could be P-K models, actuator by actuator. Average DASD response time for the system is obtained from accumulation of the individual actuator response times.

The aggregation view is capacity planning motivated. In contrast, individual device models address performance recommendations.

The P-K model, aggregate or individual, assumes that I/O requests come at random to be serviced by a server (the actuator) whose service time distribution has a squared coefficient of variation of C. It is frequently referenced as the M/G/1 queueing model. The estimation task is that of finding a C value that results is acceptable prediction error on RT/ST. In general terms,

$$RT/ST = (1 - B \cdot (1 - C)/200)/(1 - B/100)$$

Based on the author's data, good aggregate predictions are obtained for C = 10. In that case

$$RT/ST = (100 + 4.5 \cdot B)/(100 - B)$$

When 1.2 < RT/ST < 1.6, the formula yields very nearly a straight line. FIGURE 4 illustrates the fit. This model is somewhat less accurate than the SKEW Model and has an average absolute error of 8 %, approximately. Apart from its lower predictive accuracy, this model has conceptual difficulties: it is very hard to justify C = 10 as the service time descriptor. In fact, estimates of data analyzed by the author indicate C = 1.5 or so (<8>, APPENDIX II). Further, I/O request interarrival times are not random. Whatever is the distribution, its mean varies hour after hour as the workload intensity varies. Calibration of C to fit with a specific installation's data is possible if one stipulates constancy of C for that installation for lengthy time periods (several months as a minimum) to make this approach workable.

The last difficulty with the P-K model is the fact that the number of concurrently active I/O operations targeted to any one actuator is always very finite whereas the model is that of an open queue, that is one with an infinite source. To remove this difficulty, one would have to use an M/G/1/T model with a maximum number, T, of concurrently active I/O tasks. The range of 1 - 6 for T would be practical for most individual device models while a somewhat higher number could be argued for the aggregate server model. The conceptual problem changes to stipulating a reasonable multitasking level, and justifying the assumption about an even larger C than that of the open P-K model. The latter case is even less defensible than the original problem. Numerical solutions can be obtained for any non-negative C and positive integer T by following the developments of <10>.

Just as the SKEW model necessitates the inclusion of path loadings logic, the M/G/1/T model requires some underlying logic to represent these loadings. Finally, there is the problem of time-varying average server utilization. The latter is discussed further in the QUEUEING INTERPRETATION Section along with an interpretation of the plausibility of the C = 10 assumption.

SERVICE TIME MODEL

All of the above response time models assume some given ST. In fact, ST is a variable that needs to be predicted from more primitive data. Having analyzed over 20 installations and many shifts of ST data the following estimator has been developed for ST and is used in the CONFIGURATION EXAMPLES Section:

$$ST = 2 + 1.6 \cdot CT + 8 \cdot FNCH + 3 \cdot FNDE + 4 \cdot FR50 \qquad (3)$$

It states that the ST difference between two systems, one with all cache, the other one with no cache is 8 ms, on average. Consideration is given to the fact that some number of I/Os require full DASD service (read miss and write I/Os). Specific representation of detailed cache behavior is not attempted. Rather, aggregate system behavior is studied and is approximated.

Further, the ST difference between XA supported D and E type 3380s and standard type 3380s is 3 ms, on average. Finally, 3350 type actuators add 4 ms to ST over and above their longer connect time contribution (3 ms•1.6 = 4.8 ms).

The formula has been validated with data gathered by the author as of at the time of writing and was found to have an average absolute error of 7 %. It is noted that the 3350 presence in the configurations measured was very small. As a result, ST estimates with significant 3350 presence might be less accurate than stated. Graphical illustration of the relationships is not readily possible due to the presence of four independent variables in the definition of ST.

Equation (3) attempts to give a simple relationship, not necessarily one with the smallest possible error. The average service time impact of other DASD technologies could be similarly approximated once performance experience becomes available from a sufficient number of installations.

RESPONSE TIME STABILITY

The average DASD I/O response time, RT is a random variable as is the average DASD I/O service time, ST. Responsiveness of two systems with the same RT but with different ST may be perceived differently by their respective users even when all other conditions are identical. The one with higher RT/ST has more variability (less predictability) of its DASD response with concomitant undesirable fluctuations in its overall transaction response time. Thus, high RT/ST should be avoided.

When faster I/O devices are introduced (with much reduced ST) some increase in RT/ST can be tolerated as the resultant RT is also much reduced. Compromises are necessary, though. As an example, halving ST should not be accompanied by doubling RT/ST, that is by preserving the same RT as before. Rather, one should aim for a reduced (not necessarily halved) RT and for a somewhat increased RT/ST. Put differently, new technology should not be a mere replacement for the old one, rather, it should be an improvement - the story of data processing during the last three decades.

LDR PERSPECTIVE: GENERAL COMMENTS

To quote from <6>: "... a system with 2N like components cannot do twice the work of one with N like components of the same type." A quantification of this law of diminishing returns was stated in <6> and refined for actuators in <7>. It is restated below.

DASD N	Expected D.TRF (ms/s)	DASD N	Expected D.TRF (ms/s)
8	1100	28	3500
12	1640	32	3920
16	2130	40	4700
20	2600	48	5360
24	3070	60	6100

when N > 60, D.TRF = 2500 + 60•N

Another view of this phenomenon was expressed in <5> through the idea of SKEW. McNutt defined SKEW as the highest observed (on some actuator) I/O rate divided by the I/O rate of the "average" actuator. He showed that this SKEW increased with the size of the actuator pool: the more actuators in the DASD pool, the fewer I/O per second are processed by the average actuator.

The current analysis examines SKEW in terms of traffic (ms/s), rather than in terms of I/O rates. As in <5>, the SKEW increases with the DASD pool size. The author's data leads to the approximate relationship

SKEW = 4.2 + 0.02•N +- 2 (4)

The observation scatter is shown on FIGURE 5. The relationship is weak but visible (correlation is 0.7).

The LDR as stated in <6> and <7> addresses the question: how many actuators are needed to handle a specific level of DASD traffic with "reasonable" (1.3 < RT/ST < 1.4) responsiveness. The Calibrated SKEW Model leaves the definition of "reasonable" to the user and addresses the question: how many actuators are needed to handle a specific level of DASD traffic with a specific DASD response time, for specific DASD path loadings. The algebra is given below. Examples of its use are discussed in the next Sections.

When B is between the limits 2 and 2 + 0.4/SLOPE, that is between 2 and 2•(60/SKEW - 1), it is expressed from (2) through the relationship:

B = 2 + 5•((RT/ST)/SF - 1.2)•(60/SKEW - 2) (5)

with SF, the stretching factor defined as

SF = 1 + 0.01•(PB - 8)

Outside of these limits the RT/ST value is impractical for the commonly encountered DASD configurations.

APPLICATION: THE CONFIGURATION TASK

A typical configuration task would entail finding the number and type of actuators and the number and type of DASD CU's for given S (DASD I/O rate per second) and RT, CT, responsiveness targets (low and high RT/ST) and SKEW target. One could examine different configurations for various PB levels.

N is obtained from the DASD traffic definition:

D.TRF = S•ST = 10•B•N

or,

N = S•ST/(10•B) (6)

This N value is used to verify the SKEW target's likelihood of attainment by using (4). If the target is between the calculated limits it is considered achievable. Otherwise, an N' is calculated for a probable SKEW level of 4.2 + 0.02•N, a sometimes necessary step.

CONFIGURATION EXAMPLES

Configure a DASD system with RT = 18 ms and RT/ST = 1.35 that will handle 400 I/Os per second. This and the other examples are originated in the companion paper <8>. It is expected that CT = 5 ms and SKEW = 7. These CT and SKEW assumptions match the validation data closely (FIGURE 10). Consider 3380 type D and E DASD only.

Based on the specifications ST = 18/1.35 = 13.33. To apply (3) we observe that FR50 = 0 and FNDE = 0. Now, ST = 2 + 1.6•5 + 8•FNCH = 13.33. That gives FNCH = 3.33/8 = 0.42, i.e., 58 % of the DASD CUs should be cache controllers.

Total DASD traffic is D.TRF = 400•13.33 = 5332 ms/s. Total DASD path traffic is P.TRF = 400•5 = 2000 ms/s.

Consider various path busy levels. Explore DASD paths for PB = 20 %, 16 % and 12 %, respectively. That necessitates 2000/200 = 10, 2000/160 = 12.5 and 2000/120 = 16.7 DASD paths, respectively. In round numbers we need 5, 6 or 8 DASD CUs, 3, 4 or 5 of which should be cache controllers, respectively.

Apply now (5) to calculate B for different PBs.

B = 2.18 when PB = 20 %
B = 3.64 when PB = 16 %
B = 5.22 when PB = 12 %

Application of (6) gives the N values, respectively:

N = 5332/21.8 = 244 (to the nearest multiple of 4)
N = 5332/36.4 = 148 (to the nearest multiple of 4)
N = 5332/52.2 = 104 (to the nearest multiple of 4)

FIGURE 6 summarizes this and 3 other examples, the latter ones with somewhat modified conditions. FIGURE 7 is another set of 4 examples, each with S = 480, and otherwise similar to the first set. The SKEW target of 7 leads to configurations most of which when reevaluated by applying (4) end up with probable SKEW estimates plus or minus 2 units within the target. These configurations are, therefore, accepted as plausible ones. The others are recalculated for the nearest integer SKEW value.

Another set of calculations is performed in FIGURE 7 for the assumption that SKEW = 4 is possible to achieve. Finally, the original LDR guidelines are used to estimate the number of actuators required for the various D.TRF levels. A comparison can now be made between the various ways of configuration approaches.

Example details are clarified through the following notes.

• High RT/ST gives less stable response than lower RT/ST for equal average response times.

• Low path busy is usually a good idea: increased CU cost is offset by greater reduction in actuator cost. However, watch out for exceptions.

• Probable skew is obtained from the formula:

SKEW = 4.2 + .02•N

Recalculation of N (actuators) is done using (5) and (6).

• Note that not all the calculated configurations are practical. Normally, a maximum of 32 actuators would be configured on a Control Unit. As a result, configurations with N > 32•CUs are rejected.

ACTUATOR TYPE MIXING: THE HALF AND HALF CASE

Other configurations can be analyzed, as well. Consider a case with 50 % D/E and 50 % STD type 3380 actuators, an extension of the examples shown on FIGURE 7. This is the "half and half" case, H/H.

The service time calculation according to (3) gives

ST = 8 + 8•FNCH + 1.5 + 2 = 11.5 + 8•FNCH

If RT = 18 ms, RT/ST = 1.35 then ST = 13.33 ms and FNCH = 0.23, while if RT = 29 ms, RT/ST = 1.35 then ST = 21.48 ms and FNCH = 1.00. To cover the possibilities of FIGURE 7, we get

Case	H/H	H/H	H/H	H/H
RT (ms)	18	18	29	29
RT/ST	1.35	1.50	1.35	1.50
ST (ms)	13.33	12.00	21.48	19.33
8•FNCH	3.33	2.00	8.48	6.33
FNCH	.23	.06	1.00	.98
PB = 20 %				
CU's	6	6	6	6
with cache	5	6	0	0
PB = 16 %				
CU's	8	8	8	8
with cache	6	8	0	0
PB = 12 %				
CU'S	10	10	10	10
with cache	8	9	0	0

The numbers of DASD CUs and actuators are the same as those on FIGURE 7, the numbers of cached controllers are different due to the differences in the calculated FNCH values. More cache controllers are required than in the D/E case to compensate for half the actuators being the slower STD type. Also, fewer cache controllers are required than in the STD case, representing the improved responsiveness of half the actuators (the D/E types).

To avoid the tedium of applying (5) and (6) to several configuration possibilities, the N values have been tabulated for selected PB, SKEW and RT/ST levels in FIGURE 9, the Generalized LDR for actuator traffic, for a D.TRF of 10000 ms/s. Other traffic levels proportionally increase or decrease these N values. As an example, when D.TRF = 5332, SKEW = 7 and RT/ST = 1.35 the PB = 20 % table shows that

N = 460•5332/10000 = 244

Note that the DASD LDR suggests N = 125 actuators for D.TRF = 10000 ms/s (N = (10000 - 2500)/60 = 125). FIGURE 9 highlights the N values that are (approximately) 125 to indicate the SKEW, PB and RT/ST levels at which the SKEW Model and the LDR Model meet.

ACTUATOR TYPE MIXING: VARIABLE PROPORTIONS

Now, assume that half the controllers are cached. Following the examples of FIGURE 7 we obtain ST = 14 + 3•FNDE and see, readily, that the RT = 18 ms and RT/ST = 1.35 or 1.50 requirements cannot be met. Suppose that we aim for RT = 23 ms and RT/ST = 1.35 or 1.50. Now, the ST targets are 17.03 and 15.33. That gives FNDE = 1.0 and 0.4, respectively. Investigate now the condition that S = 512 I/O per second and PB = 16 %.

In the same manner, one can stipulate S, PB, RT, CT, FNDE and FNCH with SKEW and RT/ST targets to end up with a variety of possibilities. As an example, let PB = 16 %, RT = 20 ms, S = 512 I/O per second, CT = 5 ms and FNCH = 0.25 with approximate targets of RT/ST = 1.5 and SKEW = 7.

Now, P.TRF = 512•5 = 2560 ms/s. When PB = 16 %, 8 CUs are required, some with cache. The calculations are summarized below.

Option	1	2	3	4	5
S	512	512	512	512	512
RT	20	20	20	23	23
SKEW	7	7	7	7	7
FNCH	0.25	0.25	0.25	0.50	0.50
FNDE	0.75	0.50	0.25	1.00	0.40
ST	14.25	13.50	12.75	17.03	15.33
RT/ST	1.40	1.48	1.57	1.35	1.50
D.TRF	7296	6912	6528	8719	7849
N at 10000	194	133	97	275	122
N at D.TRF	142	92	63	240	96
3380 D/Es	36	44	48	0	56
3380 STDs	104	48	16	240	40
CUs	8	8	8	8	8
with cache	6	6	6	4	4

A comparison of Options 1 and 3 shows 64 actuators (mostly D/E type, Option 3) accomplishing the work of 140 actuators (mostly STD type, Option 1) at the same RT but at somewhat higher (less stable) RT/ST. Option 2 is a compromise solution. Similarly, in Option 5 the 56 E type actuators can pick up the work of 200 STD type actuators (Option 4) provided that the data stored on the 200 fits on the 56 (if not then up to 100 might be required) at the cost of some instability in RT/ST but without degradation of the average RT.

LDR PERSPECTIVE: SPECIFIC COMMENTS

The 1.3 - 1.4 RT/ST ratio originates from pre-MVS/XA environments. The pre-XA versions of RMF understate DASD RT in that software queueing of page/swap I/O requests is left out of the reported DASD RT (the reported DASD queue length, to be precise). As a result, the real RT/ST ratio is more like 1.4 - 1.5 when paging is present to any significant degree instead of 1.3 - 1.4.

Application of the LDR formula recommends 125 actuators for a DASD traffic of 10000 ms/s ((10000 - 2500)/60). Examination of FIGURE 9 shows that this number coincides with the recommendations of the Generalized LDR when RT/ST is in the range of 1.4 - 1.5, SKEW is in the range of 5 - 7 and PB is in the range of 12% - 20%.

These parameter values are encountered fairly frequently in actual installations, although, RT/ST is often in the range of 1.3 - 1.4, even in MVS/XA systems. However, the system-wide average DASD busy is generally < 8%, the level that the 125 actuators average to according to the LDR recommendations for a traffic of 10000 ms/s.

For low actual SKEW levels the Generalized LDR suggests smaller DASD configurations than those suggested by the LDR for RT/ST in the 1.4 - 1.5 range. When the SKEW levels are high, the Generalized LDR suggests more generous configurations than those calculated from the LDR formula. The two can converge after dataset placement tuning, an activity that reduces the SKEW.

PREDICTION ACCURACY

As indicated earlier, application of (2) has resulted in 5.5 % average absolute error in estimating RT/ST. Also, application of (3) has resulted in 7 % average absolute error in estimating ST. Error is computed as

100•(prediction - actual)/actual

The low error % of the RT/ST prediction is deceptive. Clearly, RT > ST for non-zero B values. Thus, one should estimate RT - ST or (RT - ST)/ST. Again, if (2) is used, we would have a 25 - 30 % average absolute error on (RT - ST)/ST, a far less impressive result. Unfortunately, other "precise" prediction models have the same problem. In consolation, the predictive accuracy of ST given by (3) is relatively good. The quantity predicted by this model is all of ST, with no large positive base to mask the huge errors of predicting an increment.

Consequences of the inaccuracy can be seen in the examples of FIGURE 6 and 7. Small changes in path loadings (PB) result in large changes in the number of required actuators. Small errors of RT/ST prediction when magically corrected would result in huge adjustments in the number of configured actuators. Viewed differently, fairly large under-configuration errors would result in relatively small performance (RT/ST) degradation. Conversely, generously configured actuator subsystems would perform only marginally better (in terms of RT/ST) than their skinny counterparts. In a tight budget environment it may be wise to err on the downside, that is to configure to a nominal specification of, say, RT/ST + 0.05 when the real target is RT/ST. FIGURE 8 shows a restatement of the example shown in FIGURE 7 in these terms. This is, effectively, a change of the ST and, therefore, the D.TRF estimate to 3 - 4 % lower values - a deliberate mistake, while leaving the RT target unchanged. The result is increased RT/ST, reduced D.TRF and reduced number of actuators. As seen, a 0.05 change in RT/ST (a 3 - 4 % change) results in 20 - 40 % change in the computed number of actuators - indeed important when a large number is recommended in the first place.

Under-configuration errors can result in minor performance degradation. Over-configuration errors will improve performance only marginally. When the data space capacity requirements of the DASD pool necessitate over-configuration, that pool will be a somewhat better than usual performer. If large data-capacity DASD is available, it is generally a good idea to configure this type of DASD at the risk of minor performance degradation when the prediction errs on the wrong side, a case that would be observed half the time.

In conclusion, RT/ST is not influenced much by DASD configuration size.

VALIDATION

Formula (2) and (3) were calibrated with data from 15 installations, each with one - five prime shifts of operation. Additional data pushed the number of installations to over 20 with more than 1200 hours of operation. Prediction error magnitude did not change with the new data. A set of data that was used in <5> and that spanned 15 minute intervals did, however, change the prediction accuracy, for the worse. These measurements featured very large SKEW values and normal (average of 4 %) DASD busy levels.

Model application to subsets of data did not result in too much change for the prediction errors. Groupings were formed as follows:

G1. daily observations, all systems;
G2. daily observations, shared DASD systems;
G3. daily observations, unshared DASD systems;
G4. summary observations, all systems;
G5. summary observations, shared DASD systems;
G6. summary observations, unshared DASD systems.

FIGURE 10 summarizes the validation results.

QUEUEING INTERPRETATION

Comments were made earlier on the inconvenience of both the M/G/1 and the M/G/1/T models. The main problem is that the average load is a random variable both in terms of time within a shift and device address within a pool of devices.

Consider a hypothetical case (also explained in <7>) of 13 actuators over a specific period of time during which 12 of the 13 have their B = 5 % and the 13th has its B = 50 %. Thus, the average of the 13 has its B = 8.5 %.

Assume that ST = 25 ms and that ST is independent of B (not true, in general). Now, the 12 actuators would process 2 I/Os each per second while the 13th would process 20 I/Os per second.

Assume, further, that RT/ST of an actuator is determined by an M/M/1 model (an M/G/1 model with C = 1): RT/ST = 1/(1 - B/100).

When B = 5 %, we get RT/ST = 1.05;
when B = 8.5 %, we get RT/ST = 1.09;
when B = 32.5 %, we get RT/ST = 1.48;
when B = 50 %, we get RT/ST = 2.00.

The average response time of the 12•2 + 20 = 44 I/Os per second is (24•1.05•25 + 20•2•25)/44 = 37.05, giving RT/ST = 1.48 - the same as that of an actuator with B = 32.4 %.

The pool of 13 actuators with average B = 8.5 % and with skewed I/O load (SKEW = 50/8.5 = 5.9) behaves the same way as a pool of perfectly tuned (SKEW = 1) actuators would in which every actuator is 32.4 % busy - a customary statement about how busy actuators can be in a "well-tuned" system. Thus, if individual actuators of an installation could be accurately described by the M/M/1 model (they cannot be) and if their DASD SKEW were approximately 6 (not unusual) this system at B = 8.5 % could be expected to look normal.

It is interesting to note that <2> reports a study of 9090 actuators (56 installations) with average B = 8.5 % for the overall pool.

Examine now the P-K mean value formula once more. We have

$$RT/ST = (1 - B\bullet(1 - C)/200)/(1 - B/100)$$

or, more conveniently,

$$RT/ST = 1 + (1 + C)\bullet B/(200 - 2\bullet B)$$

Hence,

$$C = (RT/ST - 1)\bullet(200 - 2\bullet B)/B - 1$$

If the aggregate RT/ST = 1.48 and if the aggregate response time is predicted accurately by the P-K formula then C computes to 9.33, not far from the 10 mentioned in discussing the aggregate server model earlier. Further, if the M/M/1 model above is replaced by an M/G/1 model, we obtain

when B = 5 %, RT/ST = 1 + 0.0263•(1 + C), 24 I/Os;
when B = 50 %, RT/ST = 1 + 0.5•(1 + C), 20 I/Os.

The average aggregate RT/ST is

$$RT/ST = 1 + (24\bullet 0.0263 + 20\bullet 0.5)\bullet(1 + C)/44$$

$$RT/ST = 1 + 0.2416\bullet(1 + C)$$

When C = 1, we get RT/ST = 1.48, as before.

Let C be the squared coefficient of variation of the service time of the individual actuators, Ca be that of the aggregate server. A relationship can now be calculated between C and Ca as follows.

$$1 + 0.2416\bullet(1 + C) = 1 + 8.5\bullet(1 + Ca)/183$$

The right hand side is RT/ST for the aggregate P-K server at B = 8.5 %. Therefore, when Ca = 10, we get

$$C = (0.5109 - 0.2416)/0.2416 = 1.11$$

When C = 1.11, we get RT/ST = 1.51. If every single actuator had the same RT/ST = 1.51, their utilization would have to be B = 32.6 %.

For the example, when all the individual actuators have C = 1.11 the aggregate server has Ca = 10 - the approximation referenced earlier.

SUMMARY

A DASD configuration approach to satisfy response time requirements has been proposed. Validation has shown that the I/O service and response time predictions are quite accurate. Nevertheless, small errors in response time prediction lead to large swings in the size of the actuator pool to be configured. When one deliberately overshoots the response time target by 3 - 5 %, a realistic configuration is obtained that will perform almost on target even when the response time prediction errs on the wrong side.

Configuration swings are minimized when the DASD pool is made up of faster type devices and is aided by cache controllers. In that case one can afford to design to relatively high response time to service time ratios and work in the area of low swings as a function of responsiveness prediction errors.

The configuration approach is a generalization of the author's earlier work concerning a law of diminishing returns relative to the performance of systems of many like components.

ACKNOWLEDGEMENTS

The author wishes to thank his colleague, L. Beauchemin for his help in developing the validation procedure of this paper, as well as for his comments on the material as it went through various phases of exposition. In addition, thanks are due to R. Wicks, G. Galambos, J. Ryden and L. Duyanovich for their helpful comments that shaped the paper to its present form.

LARGE CAPACITY DASD: IS PERFORMANCE SOMETHING TO BE AFRAID OF?

Bruce McNutt
International Business Machines Corporation
San Jose, California

ABSTRACT

Technology has made possible a rapid increase in the density of DASD magnetic media. Performance analysts and capacity planners have been faced with a long and continuing succession of DASD products offering sharply larger storage capacity. With the larger capacity comes an enlarged scope of action for each actuator, and the concern that the actuator might have trouble keeping up. But so far, performance on new and larger DASD devices has repeatedly contradicted expectations by turning out to be a non-problem.

This paper investigates why it is that large-capacity devices keep turning in better-than-expected performance. The starting point of the paper is that our expectations tend to be guided by the view of a DASD device as the "server" in an M/M/1 queueing model. This view does not lead to correct intuitions about DASD performance, because it fails to take into account the task structure of I/O activity. The critical impact which task structure has on device queueing, on skew, and on arm movement is examined. By considering all of these areas collectively, it becomes clear why the task structure of I/O activity tends to favor devices with large capacity -- and why such devices tend to perform well even when we don't expect them to.

1. INTRODUCTION

Technology has made possible a rapid increase in the density of DASD magnetic media. Performance analysts and capacity planners have been faced with a long and continuing succession of DASD products offering sharply larger storage capacity. With the larger capacity comes an enlarged scope of action for each actuator, and the concern that the actuator might have trouble keeping up. But so far, performance on new and larger DASD devices has repeatedly contradicted expectations by turning out to be a non-problem.

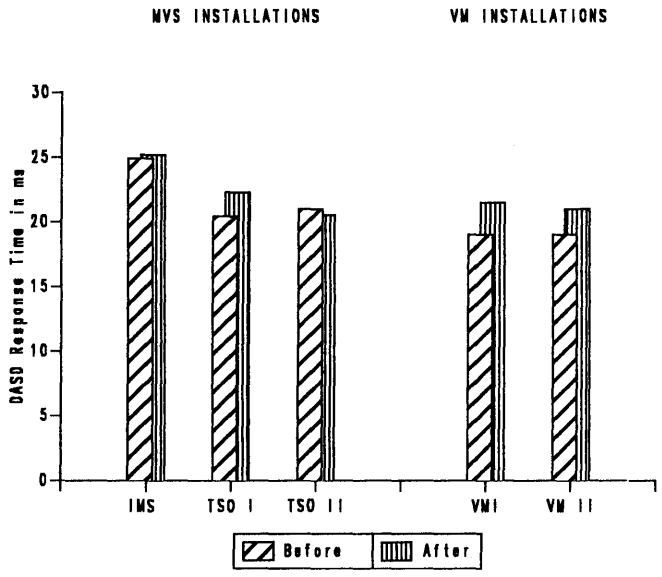

Figure 1. Results of folding at five installations: before and after

Following the introduction of the 3880 Model E DASD, which offered twice the storage capacity per arm as the previous 3880 Model A device, formal studies were done to determine the impact of the larger device size on performance [1, 2]. These studies confirmed that, as in previous cases when a device with larger capacity has been introduced, the larger capacity is not harmful in practice. Data was folded onto 3380 Model E devices at one IMS shop, and at two TSO and two VM installations. Figure 1 summarizes the overall DASD response times before and after folding as observed in these studies. At the IMS site, response time increased by roughly a third of a millisecond; at one TSO site, response time decreased by about half a millisecond; and at another TSO site, response time increased by about 2 milliseconds. The observed increase in average response time at the two VM sites was also about 2 milliseconds. At each site, the amount of data per arm was doubled or (in the IMS case) tripled; yet folding never resulted in a serious performance problem at any of the sites.

This paper investigates why it is that large-capacity devices perform so well in realistic installation environments. The starting point for the investigation is to understand better the fine-structure of the I/O activity which typically occurs on a DASD device.

In normal modeling of DASD, a very simple model of I/O fine structure is assumed. The M/M/1 technique for modelling device activity, for example, assumes that the distribution of I/O interarrival time is exponential and that each I/O is independent. The possibility of I/O "bursts" is not considered, nor is the fact that long strings of I/O's can be generated as the result of executing a single task.

Figures 2 and 3 illustrate just how far astray we can go if we accept these assumptions at face value. Figure 2 breaks down a specific sequence of I/O requests generated over a one-minute period according to the assumptions of the M/M/1 model. By contrast, Figure 3 breaks down the I/O pattern observed on a specific TSO user data volume over an identical period of time.

The average I/O rate in both figures is 2.9 I/O's per second. Each figure shows how this average rate breaks down into I/O rates observed during very short sub-intervals of time (lasting 0.1 seconds). The I/O rate in a given sub-interval is the number of I/O's which occurred during that sub-interval divided by the interval length of 0.1 seconds -- i.e., the I/O rate in a given sub-interval is ten times the number of observed I/O's. As Figure 2 shows, the M/M/1 requests are spread out more or less uniformly across the one-minute period. This uniform spreading contrasts sharply with the bursts of activity in the live data of Figure 3.

Although Figure 3 refers specifically to a TSO user data volume, bursts of activity of the type which the figure illustrates are also typical of IMS and CICS data base volumes and of VM user data volumes (a broader discussion of I/O bursts as seen on a large number of VM DASD appears in [3]). Note that despite the average I/O rate of 2.9 I/O's per second, the device is idle most of the time. It becomes active when some task initiates a rapid sequence of I/O's -- usually without interference from other tasks. Figure 3 shows that during such a burst of activity, the I/O rate may briefly reach 60 to 70 I/O's per second. Since the burst is initiated by a single task, however, it does not cause queueing.

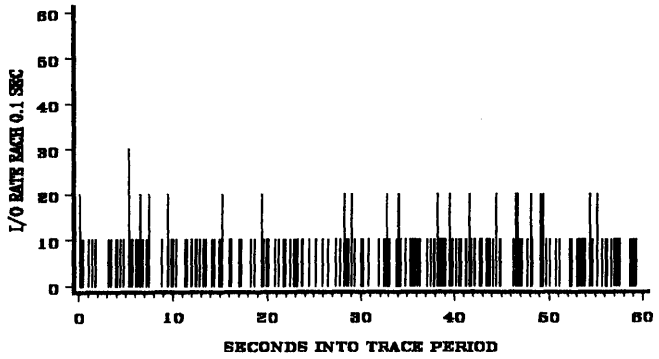

Figure 2. Poisson arrival I/O rates for each 0.1-second sub-interval of a one-minute period. Average I/O rate = 2.9

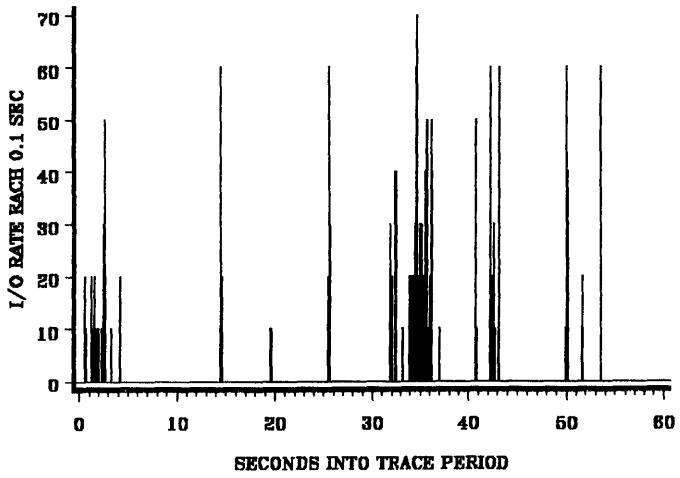

Figure 3. Traced TSO volume I/O rates for each 0.1-second sub-interval of a one-minute period. Average I/O rate = 2.9

As long as tasks do not interfere seriously with one another, there is every reason to use the largest available size of DASD device. The cost per megabyte of storage decreases with the size of the device; and at the same time, the actuator is able to handle the demands of any one task without much difficulty. Figure 3 makes clear that the opportunity to achieve *both* economic storage *and* good performance may be missed if the decision is guided by reasoning based on the M/M/1 model.

There is no claim here that large capacity devices are always the best choice for every type of data -- only that the choice of the most suitable device depends upon the fine structure of the I/O pattern. A pool of performance-critical system volumes containing data in use by large numbers of users -- e.g., master catalogues, heavily used program libraries, IMS long message queues, Resource Access Control Facility (RACF) data -- should not be folded 2-to-1 onto a larger capacity device. In this case, too many tasks may end up using a single actuator at the same time.

On the other hand, we do not need to be as cautious when it comes to data base and user data volumes. This is because active tasks are usually spread thin across such a pool. The thin spreading of tasks tilts the odds in favor of the devices of the pool being able to perform well even if their capacity is large. In particular, for both small-capacity as well as large-capacity devices containing data base and user data storage,

1. the small number of tasks using a device at any one time limits the degree of device queueing,
2. peak I/O rates are associated mainly with surges of single-task activity, and
3. seek times are dominated by the activities of individual tasks.

Since performance is mainly a function of individual task behavior, the performance provided by a larger-capacity device can rival that provided by a smaller device.

In the rest of the paper, we build a better understanding of the impact of I/O fine structure by investigating each of the phenomena (1 - 3) in turn. Some new data on device queueing are presented, and we also pull together the results of previous studies on skew [4] and on arm motion [5], with a focus on how the results of these studies bear on the performance of large capacity devices.

2. DEVICE QUEUEING

The M/M/1 model is so widely used, so powerful, and so easily applied that the temptation to think of a DASD device as the "server" in an M/M/1 queueing model is very hard to resist. This view may, in fact, closely approximate a few I/O devices on the system such as a paging device or the volume containing a heavily used master catalogue. Highly active system volumes of this kind, however, are not typically candidates for folding onto larger capacity devices. Usually, the impetus to use large capacity devices is caused by increasing demands for data base storage and storage of user data. On a typical data base or user data volume, the pattern of activity departs drastically from the assumptions of the M/M/1 model.

Figure 3 presents a good explanation of how this departure occurs on one specific device. But to see how dangerous an unqualified reliance on the M/M/1 model can really be, it is necessary to try applying it to all of the volumes at an installation. The result of doing this at nine large CICS, IMS, and TSO installations is presented in Figure 4.

The data analyzed in Figure 4 were obtained as the result of an ongoing project to collect live DASD workload data. Other results of this project and additional details about the collection of the data are given in [4]. Figure 4 is based on examining a single peak-period Resource Measurement Facility (RMF) interval at each of the nine MVS/XA installations at which data were collected. Altogether, 3255 volumes were observed at the nine installations. For each volume, the RMF queue length data was examined. The average queue length is a measure of total queue activity; it is equal to the product of queue time and I/O rate. In other words, the average queue length is the sum of the time per second spent on the device queue by each task.

Figure 4 shows a detailed analysis of the 53 volumes of the study which had a sufficiently high utilization, during the period being examined, so that the M/M/1 model would predict a queue length of at least 0.2[1]. The RMF data for each volume of Figure 4 are shown as a single point. The average queue length observed on the volume, plotted on the vertical axis, is compared to the M/M/1 estimate of the average queue length on the horizontal axis. The M/M/1 estimate is computed as

$$L = \frac{\rho^2}{1-\rho} \qquad (1)$$

where ρ is the utilization of the device as reported by RMF.

The various volumes shown in Figure 4 appear to fall into two categories:

[1] Volumes on which active multi-host sharing caused extreme amounts of pend time are not included, however. The contention mechanisms, such as reserve/release, which arise in the case of shared DASD are different from ordinary device queueing of the type being considered in Figure 4, and in practice their effects can be more severe. Also, it is not clear how to take into account extreme amounts of device pend time in applying the M/M/1 model.

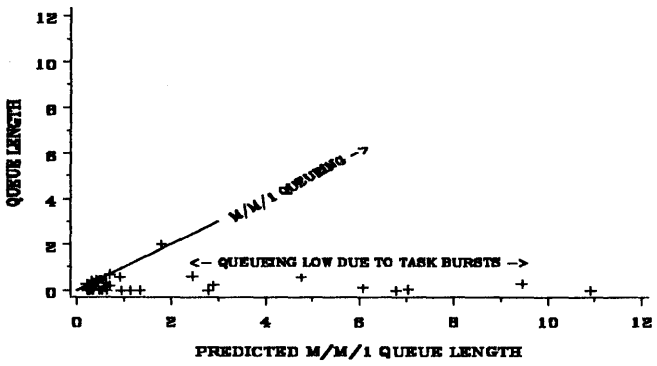

Figure 4. Tests of the M/M/1 model: predicted and actual queue length

1. volumes for which the M/M/1 model works, which lie along the 45 degree line extending from the origin, and
2. volumes for which the queueing is much less than that predicted by the M/M/1 model, which lie in a flat band along the bottom.

Volumes of type (2) can sustain very high loads without paying much of a penalty in queueing time. Utilization levels for these volumes occasionally reached 80 or even 90 percent. For a utilization of 80 percent, the M/M/1 model would predict a queue length of 3.2; yet the queue length along the flat band never exceeds about 0.6.

On the other hand, load levels of 80 percent on a volume with M/M/1 behavior can quickly result in loud complaints about response time. This helps to explain why no load levels this high were observed for the volumes of type (1).

Fortunately, only a minority of volumes fall into category (1). If we define these volumes formally by using the criterion that the actual queue length must be no less than 90 percent of the M/M/1 prediction, then they account for only 19 percent of the volumes presented by the figure, or 15 percent of all active volumes included in the study. The M/M/1 model works for these volumes because they are continually being shared by a large number of users.

By contrast with the minority of volumes in category (1), most data base and user volumes are *not* being shared by a large number of users at any given time. To put this into better focus, Figures 5 - 7 show a detailed breakdown of contention for the devices in three specific pools of user data, each belonging to a specific installation participating in the study described earlier. A trace of the I/O activity in each pool was used to prepare the three figures. The period of the trace was divided into very short sub-intervals (lasting 0.1 seconds) for the purpose of determining how many tasks were active at a given moment in time. A task was considered to be "active" on a specific device during a given sub-interval if the task produced at least one I/O to the device during this period of time.

Figures 5 - 7 present the frequency with which no tasks, one task, two tasks, or three or more tasks were observed to be active on a given device based on the three sets of I/O traces. Figure 5 presents data for an IMS data base pool of forty-six 3380 Standard volumes with an average I/O rate of 4.4 I/O's per second; Figure 6 presents data for a TSO user data pool of sixty-seven 3380 Standard volumes with an average I/O rate of 2.2 I/O's per second; and Figure 7 presents data for a VM user mini-disk pool of twenty-eight 3350 volumes with an average I/O rate of 3.1 I/O's per second. For each of these pools, the devices were idle (not being used by any task) most of the time. If a device was not idle, then it was probably being monopolized by a single task; and if it was not being monopolized by a single task, then it was probably being used by exactly two tasks. Thus, most queueing involved two tasks which took turns on the device.

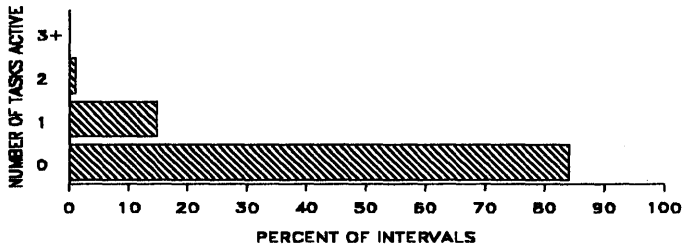

Figure 5. Histogram of the number of active tasks: 46 IMS data base volumes

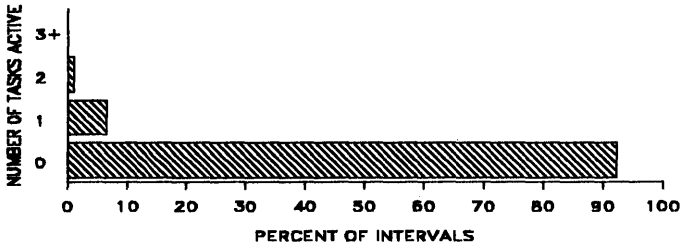

Figure 6. Histogram of the number of active tasks: 67 TSO user data volumes

It is interesting to compare the M/M/1 prediction of queue length given by (1) with the behavior of a queue in which two tasks take turns in using the device. In the latter case, the queue length can never exceed unity no matter how heavily the device is utilized. But in the M/M/1 case, it is possible for the predicted queue length to become arbitrarily large, depending on the value of the utilization ρ. The comparison becomes even more dramatic if the device is monopolized by a single task, since in this case it is not even possible for queueing due to contention between tasks to occur[2]. Since the cases of single-task monopolization and two-task sharing are the most common cases of device use, it is not hard to understand the dramatic failure of the M/M/1 queueing model as shown in Figure 4.

It is interesting to ask whether queueing would continue to be so well-behaved if the pools of data represented in Figures 5 - 7 were folded 2-to-1 onto larger devices (the 3350's onto 3380 Model D's and the 3380 Standards

[2] Since some queueing can occur even in the absence of contention between tasks, the queue length may not be precisely zero in the case of single-task monopolization. For example, both QSAM and BSAM are capable, under some circumstances, of "stacking" more than one request from the same task onto the queue for the same device.

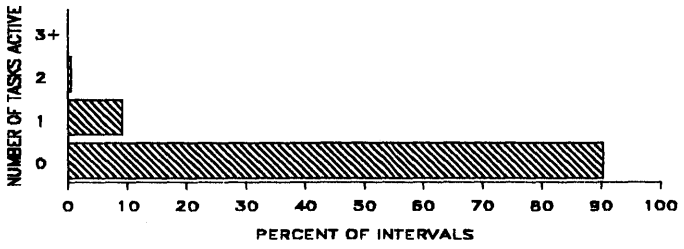

Figure 7. Histogram of the number of active tasks: 28 VM user mini-disk volumes

onto 3380 Model E's). This question can be answered by referring again to the same data used in preparing the three figures.

Suppose that in folding one of the pools presented in Figures 5 - 7, each folded pair of volumes is chosen at random from the original volumes of the pool. Then the probability that a given folded volume has a given number of tasks active in each sub-interval can be calculated combinatorially. For example, the number of volume pairs with two or more tasks active is the number of pairs in which both members of the pair have at least one task active, plus the number of pairs in which one member is idle and the other member has two or more tasks active. When this calculation is applied to the IMS data of Figure 5, the probability of two or more tasks being active increases from .0097 in the non-folded case to .0416 after folding. For the TSO data of Figure 6, the probability increases from .0118 to .0280; and for the VM data of Figure 7, the probability increases from .0057 to .0197. In each case, the probability increases but remains *very* small. Queuing would continue to have little impact on the performance of these pools of data.

It should be noted that a number of models of DASD activity more sophisticated than M/M/1 are currently available in the form of packaged analysis tools [6, 7]. Models capable of describing the CPU and associated DASD as a closed system are of particular interest. Although these models do not usually account in detail for the number of tasks using each device, they do account for the fact that a specific finite number of tasks (the multiprogramming level) are running in the system at any given time. This limits the total amount of queueing which can occur across all of the devices, and greatly improves the realism of the results.

3. SKEW

I/O rate "skew" across the volumes of an installation has a critical impact on the effectiveness of large-capacity DASD, because skew dictates the volume loads which will result from folding larger amounts of data onto each device. Two contrasting extremes help to illustrate this:

1. No skew: I/O activity is divided uniformly across all devices. In this case, 2-to-1 folding of data onto a larger capacity device doubles the load on every device.
2. Maximum skew: all I/O activity is concentrated on a single device. In this case, 2-to-1 folding of data onto a larger capacity device does not cause any change to the load on the single device which is being used.

Obviously, realistic skews exist somewhere between these two extremes. In most installations, however, the distribution of the I/O across volumes is *very* uneven. As a result, the impact of 2-to-1 folding is described better by (2) than by (1).

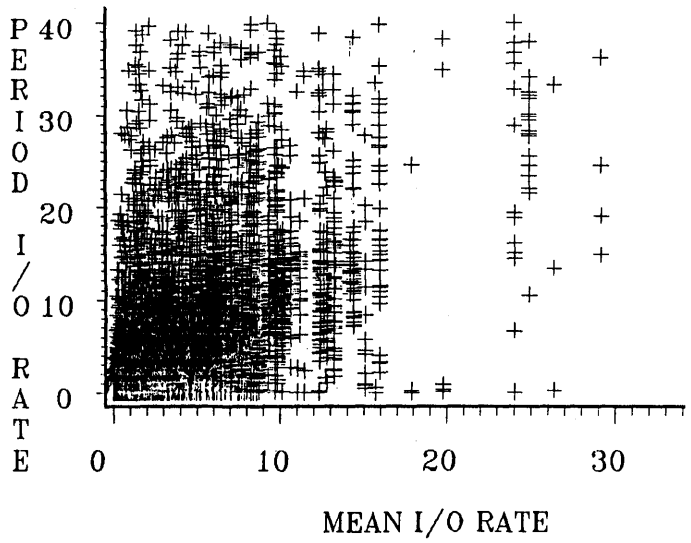

Figure 8. Variability of I/O rates on data base and user data volumes

Sharp skews are the norm because a typical installation supports a wide variety of activities. The amount of I/O generated by a given task running on the CPU is highly unpredictable, as is the specific set of DASD to which the task's I/O is directed. Figure 8 illustrates the chaos which results. This figure is taken from [4]. It shows the I/O rates which were observed on 2879 data base and user data volumes, at ten installations, during a day's worth of peak-load RMF intervals.

Each point of Figure 8 corresponds to a single volume observed during a single RMF interval. The I/O rate of the volume during this specific interval is shown along the vertical axis, and the average I/O rate of the volume over the entire day is shown along the horizontal axis. As the figure makes clear, the activity of a given data base or user data volume during a given RMF interval is extremely unpredictable.

Although it is difficult to predict the behavior of a single volume, however, we can certainly attempt to predict the statistical behavior of a group, or pool, of data base or user data volumes taken collectively. Each volume of the pool can be viewed as an observation of a random variable. This random variable, in turn, is the sum of other random variables associated with the activities of individual tasks. In [4], this approach is applied to obtain statistical predictions of skew, based on data observed at the ten installations described above.

	PREDICTED HIGHEST I/O RATE WHEN N IS ...						
	8	16	32	64	128	256	512
A							
1	3.8	6.1	9.8	14.7	21.7	29.4	36.9
2	6.8	10.5	15.8	22.6	30.6	38.0	44.2
4	12.1	17.7	24.6	32.7	40.2	46.7	57.6
8	21.2	28.6	36.9	44.6	52.3	62.6	71.6

Figure 9. Predicted I/O rate of the busiest of N volumes, given an average volume I/O rate of A

To understand the effect of folding on skew, it is useful to examine the I/O rate of the most heavily used volume. Figure 9 presents the statistical predictions of the I/O rate to the busiest device which are developed in in [4]. The figure shows how to project the I/O rate for the busiest of N active volumes, assuming that the average I/O rate across the N volumes is A.

The result of 2-to-1 folding is to increase A by a factor of two and to decrease N by a factor of two. Figure 9 shows that, in a statistical sense, the

combination of these two changes causes only a very slight increase in the load being placed on the busiest volume. For example, suppose that before folding a pool of 32 user volumes has an average I/O rate of 2 I/O's per second. Then before folding, the projected I/O rate to the busiest volume is 15.8 I/O's per second. After folding, the projected I/O rate to the busiest volume is 17.7 I/O's per second. By examining this case and a variety of others like it, it is easy to verify from the figure that folding is unlikely, *by itself*, to introduce new performance problems if the per-device loads are light enough so that folding makes sense.

Again, the claim is not that performance problems don't happen -- only that they are unlikely to be caused by taking a pool of data base or user data volumes which has reasonably light average utilization and folding this pool 2-to-1. This point is made clearer by reflecting for a moment on how DASD performance problems actually *do* occur. When the phone rings and fire fighting is needed, what does a performance analyst look for first?

The first suspicion is usually that there is some specific data set performing a system-wide service which is receiving more use than it can handle. Examples would be master catalogs, global indexes, load libraries, paging data sets, RACF data sets, and so forth. If a data set of this kind is used too heavily *by too many different users and tasks*, then a performance problem will result. This will happen regardless of whether small or large capacity devices are used, since the data set has to go *somewhere*.

It may also happen, of course, that two or more data sets which are used heavily by many users are placed on the same volume. This may even be done on purpose, if the data sets are logically related to each other -- not by the performance staff of course! If the pool of *system* volumes is folded 2-to-1, then folding may create performance problems due to this effect. This is the reason that 2-to-1 folding is safer on data base and user data volumes than it is on system volumes. Nevertheless, it is interesting to note that the same problem also occurs on small-capacity devices, and can be fixed equally well on either a small- or large- capacity device by separating the highly active data sets onto different volumes. In most cases, the problem can also be fixed (and a considerable performance benefit achieved as well) by placing highly active system data sets of this kind under a cached controller.

4. ARM MOTION

Arm motion is another area where the task structure of I/O is important. The tendency for single tasks to dominate the use of a given device has a highly beneficial impact on the seek times of any sort of DASD, regardless of size. We review the effect in this paper because a large-capacity device still sees most of this benefit, despite its size.

The impact which the task structure of I/O has on typical device seek times is dramatic. For example, the seek time required for a seek between two random locations on a 3380 Model D device (the so-called "nominal" seek time) is 15 milliseconds. On a 3380 Model E device the nominal seek time is 17 milliseconds. Yet, true average seek times on 3380 Model D and Model E devices operating in live environments are typically in the range of 2 to 7 milliseconds [5].

Real average seek times are so much smaller that "nominal" seek times because if the data set being requested by a given I/O was also requested by the previous I/O, then this data set is already under the arm. The arm may not need to move; or if movement is needed, the seek distance is likely to be short. Taking into account both cases of no arm movement as well as the distribution of seek distances if arm movement is necessary, the average seek time for an I/O request to a data set which is already under the arm is no more than two or three milliseconds for a device type in the 3380 family. Only occasionally is it necessary to reposition the arm to an entirely new data set, thus requiring a "nominal" seek.

This same pattern of behavior occurs on both larger and smaller capacity devices. The relationship between the two cases can be explored by asking what happens when data is folded 2-to-1 from a smaller device onto a larger one.

Before folding, each task that is active on a given device causes the arm to move according to a pattern required by the task itself. This pattern may involve both seeks within the same data set as well as "nominal" seeks between different data sets. The pattern is occasionally interrupted by the activity of some other task on the device, but as Figures 5 - 7 suggest, the level of interference is minimal. The overall seek time is dominated by the seek activities of individual tasks.

As the result of folding, the level of interference between tasks must increase, and hence some new "nominal" seeks must occur. But how significant is this added arm motion compared to the arm motion associated with the activity of the various individual tasks of the system, absent any interference with each other?

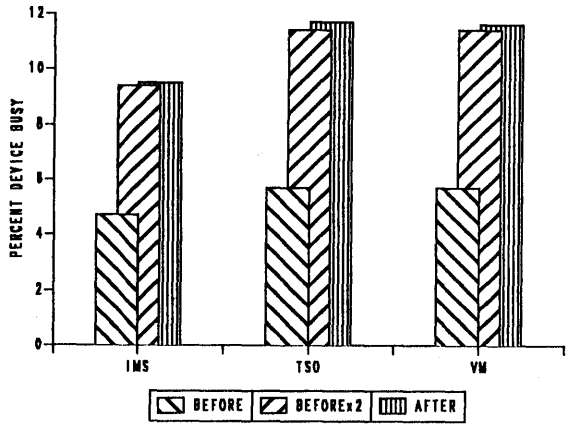

Figure 10. Impact of 2-to-1 folding on device utilization for three pools of data

A detailed examination of this issue is performed in [5]. Using GTF and VM Monitor seek traces, the seek times before and after folding are computed for several pools of data, including IMS data base storage, TSO user data, and VM mini-disk storage. The pairing of volumes is taken to be random; pairs of volumes whose I/O patterns take turns are taken into account, as well as pairs whose I/O patterns conflict.

A summary of the impact of folding on device utilization in the TSO, IMS, and VM case studies of [5] is presented by Figure 10. For each pool, the figure shows the utilization per volume prior to folding and after folding. For comparison, the figure also shows the utilization per volume which folding would have produced assuming no change in seek times (exactly twice the original utilization per volume). As the figure makes clear, the added utilization caused by additional seek time is insignificant. The arm motion required by the activities of single tasks predominates over any arm motion caused by contention between tasks, and this is true both before and after folding[3].

5. CONCLUSION

As we have seen, active tasks tend to be spread thin across data base and user data volumes. These volumes spend most of their time either idle or being monopolized by a single task. Long periods of inactivity alternate with short bursts of high demand. Since the high demand is usually created by one task at a time, such demand does not create additional queueing or lengthen device seek times. Thus, these volumes are likely to perform well even if they are used to store large amounts of data. This has encouraged the introduction of a long and continuing succession of DASD products offering sharply higher capacity per volume.

[3] [5] puts these statements into a more quantitative framework. Using a combinatorial technique similar to that of Section 2 of this paper, the mild impact of 2-to-1 folding on seek time can be shown to be the direct result of the fact that "accidental" arm steals between data sets, as caused by task contention, are unimportant.

Meanwhile, the cost advantages of increasingly large storage media have not been lost on the developers responsible for new data base applications. It has been possible to cost-justify new applications with increasingly large storage demands. On the average, such applications tend to further thin out the density of tasks with respect to the data on which the tasks are operating; and this in turn further encourages the introduction of new and larger devices.

This situation has continued to evolve ever since the earliest DASD. In 1972, W. L. Lynch reported measurements of 2314 devices running under MTS (Michigan Terminal System) which showed surprisingly little arm movement [8]. The patterns of access to data base and user data volumes observed in this paper have persisted despite the more than 40-fold increase in device size between the 2314 and the 3380 Model E.

Clearly, then, these patterns do not depend on our having examined some specific generation of devices and applications. Instead, they would appear to be a stable characteristic of data base and user data volumes.

We have tested this stability further by surveying the impact of 2-to-1 folding on queueing, skew, and arm motion as observed in several test cases involving live installation data (some introduced here, others in [4] and [5]). This is a particularly stringent test, because 2-to-1 folding does not expand the data used by a given task or cause any thinning of the tasks with respect to the data on which they operate. Even so, the predominance of activity by single tasks as observed in all of the test cases surveyed continues to persist even if the data for each test case is folded 2-to-1.

It seems reasonable to conclude that the phenomenon of large devices which perform surprisingly well is likely to be be with us for some time. It is not necessary, however, for us to continue being surprised by it.

CAPACITY PLANNING FOR A MULTI-PROCESSOR ENVIRONMENT SUPPORTING CICS TRANSACTIONS

Donald T. Gantz *, Carlos M. Gonzalez *, and Melvin L. Moore **
* George Mason University, ** U.S Customs Service

ABSTRACT

In this paper we discuss an ongoing capacity planning effort at the U.S. Customs Service which has a large and growing online data processing requirement. Capacity planning is implemented for IBM 3084 and 3090 based systems running large CICS workloads under the MVS/XA operating system. Measurements on SMF and RMF data are made using as a tool Merrill's MXG software. Performance data bases are designed for efficient information retrieval and for maintenance of an organized historical record of the data. Resource delivery and performance of the system are profiled and reported using programs written in SAS. Innovative graphic summaries are used to provide succinct, informative management reports. Reporting includes status snapshots, trend analysis and projections. Data collecting and reporting are linked to a menu driven system for job submission to facilitate scheduled reporting carried out by quality assurance personnel. We discuss some of the changes that have been made as a result of this capacity planning effort.

1. INTRODUCTION

Most of the work done in capacity planning [BRO-77; BRO-79; and COR-83] has used service resource units as a measure of capacity for the system. This measurement technique addresses the question of how resources are being used and it has a potential for forecasting available capacity for future needs. Additionally, an analysis done for CICS systems [FRI-86; PAT-85; and WON-86] requires measurement of the response time of the system. Response time measurement addresses the question of how well service is being provided to users. One of the purposes of this work is to report our experiences with a management model which integrates data on resource utilization and quality of service to users. An important objective in designing the model is the use of graphics as a means to present results to management. Techniques of exploratory data analysis [CHA-83; MOS-77; HOA-83; and TUK-77] are used to obtain the desired graphical reports.

This paper is subdivided into sections which explain the working environment, the measurement tools utilized, the measurement techniques, an analysis of the results, a management perspective, and a final section of conclusions and future research.

2. WORKING ENVIRONMENT AND MEASUREMENT TOOLS

The work reported here was done for the U.S. Customs Service for their computer center located in Alexandria, Virginia. When the project started, the center had an IBM-3084 running the MVS/XA operating system and servicing more than 2300 terminals scattered throughout the U.S. The volume of work generated by these terminals was on the order of 250,000 CICS transactions per day. As the number of applications grew, the center added an IBM-3090/200 also running under MVS/XA; This machine was recently upgraded to a 3090/400. The number of CICS transactions is currently more than 460,000 per prime shift, with still more applications to be implemented. Most of the CICS load is handled today by the 3090, leaving the 3084 for all the testing and non-CICS applications.

The data center utilizes a variety of monitor and report generator tools to assist in tuning and managing the systems. In particular, OMEGAMON is used as a monitor tool and reports are generated using SLR and JARS. Reports are generated and used as needed and then discarded. There had essentially been no historic performance data base and no ongoing capacity assessment or modeling. This paper therefore discusses the first stages of setting a capacity planning capability rather than reporting on a new phase of an ongoing effort such as is reported in [KRA-86]. The initial task was to start maintaining a performance data base and to set up an ongoing management reporting process. All major SMF [SMF-87] and RMF [RMF-87] records are being journaled, and there is a considerable library of historic raw data. We decided to use SMF and RMF data for our analysis. Having chosen the accounting data as the primary data source, the next step was to choose a software system to decode this collection of records into a usable performance data base. The data in the accounting files are compatible but disjoint, with information spread across a number of different records in many sequences. Hence, we needed a good tool to facilitate this analysis. SAS has become a widely accepted standard for reading SMF data through its utilization by Merrill's MXG [MER-84] software and Morino's MICS [MOR-85] products. Merrill's MXG software is an inexpensive tool for reading journaled data and forming a performance data base of SAS data sets. Other products like MICS are more comprehensive tools for the capacity planner, but are considerably more expensive. With our background and experience with SAS and budget constraints, Merrill's MXG seemed ideal for our purposes. The MXG software provides us with an automated system that uses SMF and RMF data to build a performance data base (PDB). The PDB provides measures of resource consumption and response times, and it is our basis for analysis, reporting and planning. Merrill's MXG and SAS [SAS-85] were installed by the data center.

We set about the task of measuring and reporting what the computer is delivering and how well it is performing under its load. Our reports are to assist managers who are responsible for procurement and planning, and our measurements and reports have to be directed at these responsibilities.

Higher management are sensitive to a declared middle management separation of capacity planning and data center operations responsibilities. As a result, specification of control performance groups by the capacity planners might have appeared to constitute interference with performance tuning and data center operations. Control and report performance groups had been defined to meet the needs of computer systems operations personnel. The priority and origins of our work were not central enough to allow us to specify our needs for redefinition of the groups. We began our work constrained to live with existing definitions. As a consequence our ability to relate resource usage to the business units consuming them was affected.

Additionally, there is no formal chargeback system for data center services, and, consequently, user and job identifiers are not regimented or comprehensive. There is an effort underway to systematize user and job identifiers.

Our working relationship with the data center systems people is good, and we have accumulated the knowledge required to credibly execute our measurement and

reporting. Since Merrill's MXG is essentially a data extraction tool, we have to write our own SAS programs to manicure and analyze the extracted data and to report to management. We are well prepared for this requirement. One of the authors is an applied statistician with many years of experience in using SAS for data analysis and reporting. Further, much of this author's consulting and academic work has focused on innovative use of graphics for analysis and reporting. We have available many graphical techniques and the SAS routines to execute them.

The programming task included preparation of routines to properly clean and assemble the measured data. For instance, program statements were prepared that selected out real CICS transactions from SMF Type 110 records and purged routing and other extraneous transactions. This sort of analysis bookkeeping is particularly important to our reporting responsibilities. Management's concept of processed CICS transactions consists of the production workload that is the main business of the data center. It is important that non-business transactions generated by the system or by testing, etc., not inadvertently distort the accounting of business transactions. Additionally, it is vital for our reported work volumes to be compatible with volumes from other reports generated directly by the data center. Therefore, we not only have to be thoroughly aware of what we are actually measuring, but we have to know what is actually being measured by others.

3. MEASUREMENT TECHNIQUES

Initially data was analyzed for the whole 24 hour period in order to comprehend the nature of the business handled by the data center. After a preliminary analysis, we concluded that most of the work load was handled during the prime business working hours between 8:00AM and 4:00PM. We expanded our measurements and analysis to the period between 8:00AM and 7:00PM to include fully the west coast working hours.

We designed and implemented the procedures to create the PDB's necessary to maintain an efficient information retrieval system. At any given time we have the PDB's for :

* Daily -- for all days before the previous sunday.
* Weekly -- for all weeks of the current month, except the current week.
* Monthly -- for all months of the current year, except the current month.
* Yearly -- for all years, except the current year.
* The accumulated data for the current week.
* The accumulated data for the current month.
* The accumulated data for the current year.

Based on management's need to quickly access the information in the PDB's, we decided to keep on line only the PDB's of daily data for all the days of the current week, weekly data for last week, and the accumulated data for the current week. The rest of the PDB's are kept on tape, and updated when required.

We went through an iterative process of management review of report designs. After a comprehensive menu of reports was approved by management, we mapped back to our original PDB the variables needed to produce such reports. We then modified the MXG software for the creation of PDB's tailored to our specific needs. Thus, we left on the PDB only those variables needed to produce the required reports. This process eliminated the need for large disk storage, as well as increased speed of the information retrieval.

We created tapes with SAS data sets of SMF Type 110 records. The runs of our modified MXG programs could create data sets from the SMF/RMF data with relatively little CPU time. Below is a list of the SAS Data Sets built by the modified MXG software to create the PDB's.

Data Set	Type Title	SMF Record
TYPE70	RMF CPU activity	70
TYPE71	RMF Paging and Swapping activity	71
TYPE72	RMF Workload activity	72
TYPE73	MVS/XA Physical Channel activity	73
CICSTRAN	CICS Transaction data	110

Table 1

4. DATA ANALYSIS AND MANAGEMENT REPORTS

One of the motivations for writing this paper is to make known to other technicians some of the quantitative tools that have gone over well with management in the current work. To this end, some examples of management reports are provided. These reports either summarize a single day's processing or attempt to compare daily processing over some period of time. These reports are produced using some SAS display procedures which produce a particular type of graph, but allow specifications on style and formats. Considerable use is made of SAS's capabilities for data manipulation and summarization, general purpose programming, and report writing.

We will first discuss our reports which summarize a single day's processing. Figure 1 is a CPU busy profile for one day's prime time processing. Management can see the peak and valley pattern (persistent from day to day), the available CPU time for growth, and the variation of the pattern across CPU's. This chart was a simple product of 'PROC CHART' in SAS. Additional reports in a generally similar chart style are presented in Figures 2 and 3. Figure 2 summarizes a day's delivery of resources. Resources are measured in 'resource units' and displayed in separate charts for CICS, database and other uses. Again management can see the pattern of delivery and compare consumption for the separate uses. The information in Figure 2 is from Type 72 RMF records which measure system resource usage. Type 72 records measure CPU time delivered to specific performance groups while Type 70 records measure all CPU time consumed. Figure 3 presents information from both Type 70 and Type 72 RMF records. By combining this information, the chart in Figure 3 includes the additional category of 'overhead' CPU time. The information in these three charts is basic and of clear management interest. The same format of these charts is used to present busy patterns for channels (from Type 73 records), page rates (from Type 71 records), or other RMF data information.

The measure of how well the system is servicing its users is the response times for CICS transactions. The CICS response time measured on Type 110 records is response time within the computer, that is, internal response time. A report on response times should give information concerning the system's success at meeting service level agreements. Typically such agreements reference the fraction of users who will experience a specified interval of response times. Figure 4 presents a statistical graphic which provides a succinct picture of response times experienced by users. The statistical graphic is the Box and Whisker diagram [TUK-77]. Box and whisker diagrams summarize percentile values of a measurement. The diagram consists of a box that runs from the 25th to the 75th percentile values, and whiskers extending from the box to extreme percentiles. In the diagrams the lower whisker indicates the 10th percentile and the upper whisker indicates the 95th

percentile. These selections reflect the relative importance of outlying values in either direction. The median (50th percentile) and the mean (average) values are indicated by using the symbols 'M' and 'A', respectively. Figure 4 presents a summary of one day's prime shift CICS response times using Box and Whisker diagrams. Note that the actual number and percent of CICS transactions in each hour is also included. This report immediately tells management the fraction of users experiencing various response times, and also tells a manager how response times vary over the shift. Management has readily accepted this style of report. The report conveys clearly and crisply much more information than tables of percentiles or charts of a single percentile such as the median or the 95th percentile. In this case there are no formal service level agreements; therefore, a traditional chart indicating the percentage of users for whom an agreement is met is inappropriate.

Additional reports compare daily processing over some period of time. Each of the reports in Figures 1 through 4 has a corresponding report style combining information from a number of days. Bar charts, such as those in Figures 1 through 3, for a number days can be aggregated to a single chart that summarizes the heights of the bars for all days. When there are just a few days, or a week, the span of heights can be indicated symbolically by |----------|; if there is a reasonably large number of days, then the variation in heights can be indicated by a Box and Whisker diagram. The Box and Whisker option is used in Figure 5 which summarizes system resource units delivered for a five month period. Figure 6 breaks down the 2PM data in Figure 5 into one month cuts. The graphs in Figures 5 and 6 are each produced through a trivial modification of a single program that runs on a continually updated summary data set of Type 70 and 72 RMF records. The structure of programs and data bases allows prompt response to management's desires for particular comparisons.

The preceding paragraphs have shown separate reports on resource delivery (work done) and response times (quality of the work done). Figure 7 presents information concerning resource delivery and response times in a single report. The left half of the report tells how many system resource units were delivered at 2PM on that day while the right hand side tells how many CICS business transactions were serviced and what response times were experienced. This report is valuable to a manager in that improved or degraded performance should be visible in the report. Further, whether the change in performance is associated with a change in workload should also be reflected in the chart. Note that the bar representing system resource delivery is composed of C's, D's and O's, indicating how the resources break down by CICS, data base and other performance groups. The staff member desiring this style of graph can select from a menu allowing resource delivery to be represented by aggregate system resource units (as in Figure 7), CPU units, memory units or I/O units. Also, menu selection governs for what dates data will be displayed. Figure 7 shows a degradation in response times in late February due to certain CICS transactions becoming more complex. Also shown is the change in resource delivery due to a hardware upgrade (3090-200 to 3090-400) in mid April; here an increase in memory units accounts for the increased system resource units delivered. After the upgrade, 95th percentile response times, represented by the upper whisker, were reduced by about two seconds.

The above discussion presented the style of graphic information that our measurement effort is reporting to management. These reporting formats were worked out through the interaction of manager and technician in the attempt to get a better understanding of service delivery of the computer system. The ongoing effort is trying to extract information providing a more accurate understanding of the potential for growth in the system. The ultimate goal of the project is provision of meaningful support for acquisition planning.

To this point, our discussion has focused on reports that consisted of crisp graphic information that was readily digestible by literate managers. Now our work turns to conclusions which utilize some theoretical statistical tools. Here, when we come up with a number, we do not appeal primarily to a picture for credibility, but we also need to credit the 'black box' of statistical methods, in particular, regression analysis. From the very first conversation with management, we are asked to predict when the system will hit capacity. We will discuss some of our analyses which address that prediction.

For the first two months of operation, the 3090/400 has been running with an overhead of 18 to 20 percent of expended CPU units. Besides the CICS transactions accessing the data bases, the other workload is relatively small and controllable during the prime shift. Since the CPU units due to CICS and to the data base system are really measuring the same work intensity, both of these quantities should not appear simultaneously as independent variables in a multiple regression. If they did appear simultaneously, the sum of their regression coefficients would be a robust quantity, but the separate regression coefficients would be inconsistent. A surrogate variable for this combined CICS/data base workload is the number of CICS transactions processed. We demonstrate our application of regression analysis from that approach.

First, we subtract from the total expended CPU units the portion due to the non CICS workload. The remaining total business CPU units are then related to the number of transactions processed. The analysis is done on the busy period from 10AM to 4PM during the two months since the upgrade to the 3090/400. A scatter plot of the data showing this relationship is presented in Figure 8. This scatter plot has been cleaned of the obvious bad data and spurious outliers. Examination of the daily reports presented in Figures 1 through 4 is one step in that cleaning. A regression fit directly to the data in Figure 8 is unsatisfactory. Viewing the regression residuals will quickly indicate a bad fit to the data. However, if we focus on the data where the number of transactions is at least 40,000, a straightforward regression analysis provides an acceptable fit. The residuals for this regression fit are presented in Figure 9; note that there is no pattern in the residuals that indicates a real lack of fit. The fitted regression line is (for one hour):

CPU UNITS = 14,761,986 + 409 * CICS TRANSACTIONS.

The desire, of course, is to calculate how many additional CICS transactions will bring the system to the theoretical limit of CPU units. There are some obvious objections to this type of projection. First, we would be using our regression relationship to predict outside of the observed range of the number of CICS transactions. Also, the system has other limitations which will degrade response times before these projections are fulfilled. However, current work is proceeding using these techniques and others. As our system comes closer to having saturated periods, we will gain experience and determine which techniques work or work best.

Online Report Selection

An online menu driven system was designed and implemented. The objective of this system is for the selection of specific reports and time periods. The system runs under ROSCOE [ROS-84] using the ROSCOE Programming Facility (RPF) [RFP-84].

The system builds, verifies and submits the proper jobs for the production of the reports selected by the user from the different menus. An example of some of the menus can be seen in Figures 10 to 13.

5. MANAGEMENT VIEWPOINT

The intent of directing an effort to create a capacity planning capability in the Customs Service was to be in a position to know when we needed to proceed with procurement actions for additional computer resources. The agency now has two data centers with about 4500 terminals and micro and mini computers located in the field offices. One center has an IBM 3084 and an IBM 3090-400 with about 150 gigabytes of on-line storage. The second center now has a NAS XL 80 with 190 gigabytes of on-line storage. Additional processors of these sizes are forseen to be needed in the next few years. The data centers are connected to field offices through an X.25 packet switching network and an extensive leased line system of communications. Major new applications to support the law enforcement and commercial systems of the agency are being developed. Systems hardware procurement schedules are rather lengthy in federal agencies. Long range planning is essential if we are not to be run over by normal growth that occurs in an organization with a rapidly expanding mission, like that at the Customs Service.

Within the Customs Service there is an Operations Division with responsibility to perform the normal systems tuning effort. While the information produced by this project can be used to advantage in this effort there was no intent to provide all the systems tuning data that might be required to perform that task. Systems tuning data that might be obtained was seen as a nice by-product that could be given to the system software staff for their use. There is an organizational issue here. Each different staff has its own sense of responsibility for using capacity information. The procurement staff for the data center are not integrated with computer systems tuning personnel, each being in different sub-organizations of the agency. Therefore, conflicts of interest can arise. They should simply not be allowed to remain. It is a responsibility of anyone who wants to see himself or herself as a manager to look past conflicts to see the common good of accurate performance data. Someone may see the presence of information as a challenge to how well they do their job, and not want to have performance information available to anyone outside their own group.

Within Customs there were some basic agency management issues to be resolved that became goals of the project. These were as follows:

Procurement Planning. We want to know enough about how our workload is growing to be able to plan for acquisitions through the competitive process. We recently completed a large competitive procurement where the difference in bids versus the normal GSA list price was on the order of 35 percent. The evaluated difference in price was about 9 million dollars. These kinds of savings are available through competition. Such savings argue for not simply buying from some schedule, but rather taking a longer time to buy with competition being a money saver.

Workload Realignment. Based upon the graphing of the consumption of our computer center resources, we should be able to shift work from peak to off peak usage.

Understanding of Maximum Potential. A mystery of data processing seems to be the continual surprise that experienced personnel have at being nearly out of capacity to perform work or at being near some agreed set of performance parameters or service level agreements. We wanted to gain in our understanding of how much room to grow we have with our current and planned equipment.

Functional Change Analysis. An unspoken desire was the ability to assess the impact of certain new functional changes to the installed systems which support the major users of our data center, and to assess how performance of these new functions changed as the workload experienced rapid increases.

Budget and Project Planning. It is often the case that people who are in the business of creating capacity planning reports think that it is someone else who must use the reports or draw conclusions from them. We usually refer to these unseen or unidentified people as "top management" or use some other pointer that says "it isn't me that is holding us back from using this great data." Well, in fact, it is often the case in federal agencies that budget information and planning information flow upward from one with the information to one who will commit the funds and direct a project to proceed. In the U.S Customs Service, as in most business enterprises, the individual with well-thought-out information is in a position to make a positive contribution to senior level decisions. Often this is not through the actions of others up some mysterious chain of command but rather through our own actions. That is, we are often that unseen higher authority that needs to act on the information that we possess or can obtain by writing well-founded recommendations.

In summary, the process of building a capability to assess present and future usage of data processing resources has been difficult to implement. There are as many managerial problems as there are technical ones. The problems of clear communications where the technician can understand the intent of the Customs manager were a beginning obstacle. The reverse is of course also true of the manager coming to grips with his own changing desires for the project. This is the start of an agency's effort. The ultimate utility of the project will only be assessable after some years in operation.

6. FUTURE WORK

Work is proceeding on two fronts. Business identifiers are being used to present the kind of information we have discussed above for separate business categories of work. The effect of changes in the business workload can then be better assessed for its impact on the system [KRA-86]. We are also working on useful definitions of system capacities. The system reported on in this paper has not operated under a saturating workload. We hope to track the system as the workload increases and to support management in their decisions relative to the system.

MODEL TIMEFRAME SELECTION AND ANALYSIS OF VARIANCE OF AN ONLINE TRANSACTION PROCESSING WORKLOAD

By
Theresa A. Hellner and Dennis J. Henry
American Express Co.
Travel Related Services

ABSTRACT

This paper will demonstrate a methodology for selecting a timeframe to represent the baseline model of a central processor complex dominated by an online transaction processing workload such as IMS, or CICS. The final step in modeling a given workload is the verification process, which compares the predicted to actual results. In order to manage a forecast over it's expected lifespan, a methodology to account for the variances between the predicted and actual results is necessary. A practical application of David Vincent's methodology entitled, *"Analysis of Variance of Workloads"*, which appeared in the October 1986 issue of the EDP PERFORMANCE REVIEW is demonstrated. In closing, the authors draw a correlation between selecting a timeframe to model and the verification process. Worksheets and sample code to perform the necessary calculations for the analysis of variance are also included.

INTRODUCTION

This paper demonstrates a practical implementation of David Vincent's methodology entitled *"Analysis of Variance of Workloads"* published in the October 1986 issue of the EDP Performance Review. This method is used to account for variances in a processor complex dominated by online transactions, namely IMS. For several years the Capacity Planning department has tracked the overall actual to forecast variance of total processor utilization and IMS transaction counts. When it became necessary that a more detailed tracking of the IMS application workload was required, variance analysis was undertaken and the use of Information Planning Units (IPU) was implemented. Besides variance in transaction counts and application CPU usage, the transaction mix (arrivals and CPU time by workload) can now be accounted for. This implementation is demonstrated by the following topics:

- Representative timeframe selection
- Overview of the modeling process
- Analysis of variance using IPUs
- Practical application using an actual case
- Correlation of timeframe selection and verification
- DB2 IPU development

Capacity Planning is responsible for various data centers with IBM 3090-400 and 3090-200 processors and several smaller processors. Due to the complexity of the these centers, Capacity Planning's charter is to forecast only processor growth. I/O Configurations are the responsibility of the data center technical support staffs.

The major workload for this discussion is IMS which is the driver of specific processor upgrades and accounts for approximately 50% to 85% of the prime time processor utilization for the processors that host the IMS Subsystems. The IMS Subsystems are split by application, hence, forecasting can be done using one or two primary IMS applications as drivers of a subsystem. Data centers that forecast using IMS transaction classes can also apply the following procedure.

REPRESENTATIVE TIMEFRAME SELECTION

The following discussion concerns selecting a model timeframe for a processor whose upgrades are driven by a large IMS Subsystem. However, the same methodology can be applied to a processor dominated by other workloads. The various jobs submitted by the analyst are, in this example, based on data files in a MICS Database and indicate both the transaction volume and transaction workload mix by IMS Subsystem ID. When more than one IMS Subsystem is on a processor, the IMSID's are combined. All of the programs discussed in this paper were developed in-house by the Capacity Planning staff.

The direction given to Capacity Planning for sizing the processors is based on a representative peak processing hour, not the peak hour or the 90th percentile. The representative peak hour is actually an average of the peak processing hour of each day over a one month period of time. Days with outages during the peak volume period of Time Zone 1 are eliminated from this calculation.

Selection of a representative day and hour begins with a calendar report which shows total IMS activity within the prime shift (Time Zone 1). This program is the only one where multiple IMSID's executing on the same processor are combined to show the busiest hour by transaction volume. Days that incurred outages are noted on this report and excluded from any further processing. This report (see Figure 1) indicates by day the following information:

- total transaction volume for Zone 1
- peak hour transaction volume
- peak hour of occurrence
- CPU msec/transaction across Zone 1
- average transactions/second

Figure 2. Example of the monthly report by hour

The function of the second program is twofold. First, it produces an hourly profile of the major applications by IMSID within Time Zone 1 for the entire month. The premise is that the IMS Subsystem has one or two major applications that represent the majority of the total workload and therefore actually drives the IMS forecast. The second function is to produce a list of the potential timeframes to model. To find a representative day in terms of workload mix, the analyst must come close to matching the applications's transaction volume, and CPU consumption. Looking at one or two applications per IMS Subsystem saves time in selecting the correct day and timeframe to model.

The MICS daily IMSIAU file is used as the input. Figure 2 shows each IMSID and the major applications 90th percentile hourly transaction volume (TRANS1), and average hourly transaction volume (AVGTRANS). Figure 2 also shows the percentage of total transactions (PCTRANS), and the percent CPU busy time (PCTCPUTM) that the major applications required in relation to that of the entire IMS Subsystem. Other information on this report is the 90th percentile and average CPU time (CPUTM1 and AVGCPUTM) and response times (TRSTM1 and AVGTRSTM) per transaction for each of the major applications. As can be seen this report shows clearly that the AR application is the dominant application of this IMS Subsystem accounting for nearly 83% of the total transactions and 92% of the total CPU time over each hour of Time Zone 1.

The second report (Figure 3) produced by this program is a list of selected representative peak hours that are potential candidates for the baseline model. For each IMS Subsystem the program creates a transaction volume range based on the average peak hour transaction volume over the month. The high and low values of the range are then calculated as plus or minus 1% of the average peak volume. Hourly transaction volumes within this range are then listed in the report.

Choosing the representative hour requires the analyst to also validate that the selected timeframe does not include any system outages and that the application transaction mix is typical of the IMS Subsystem daily performance. This is verified by executing a detailed report for the day and hour chosen from Figure 3 and comparing its output to the hourly transaction volumes, CPU time per transaction, and response time per transaction for the major applications within the IMSID to that in Figure 2. The percentage of total transactions and CPU time of the applications will also be compared to Figure 2.

The particular report that is used to validate a potential timeframe to model is shown in Figure 4. The timeframe selected from Figure 3 was April 28, 1987 for the hour of 10:00. The AR application profile for this particular hour is the only one that the analyst will try to match up with the hour of 10:00 on Figure 2. As you can see the AR CPU time per transaction of 20.22 milliseconds on Figure 4 matches up very well with the AVGCPUTM of 20.3 milliseconds for the selected hour. The average response time of .46 seconds in Figure 4 matches to the AVGTRSTM of .46 seconds on Figure 2. The percentage of transactions and the percentage of CPU time that the AR application represent, 84.9% and 93.5% respectively, of the total IMS Subsystem on Figure 4 are slightly higher than the average of 82.85% and 91.96% shown on Figure 2. Since this day is a representative peak timeframe that difference can be attributed to transaction volume.

The key here is that the driving application's (AR) profile for this particular IMS Subsystem during this timeframe fits very nicely with the profile for the hour of 10:00 shown in Figure 2. This timeframe is a good candidate for the baseline model.

SELECTED REPRESENTATIVE PEAK HOURS

OVERVIEW OF THE MODELING PROCESS

Once the representative hour is selected for a processor, the baseline model is created using BEST/1 or another modeling system. The processor utilization, arrival rates, and the IMS average response times are validated. The forecast is then applied to project growth over the required timeframe (for example two years).

Capacity Planning gathers forecast data using expected normal business growth, the addition of new IMS applications, and anticipated growths of existing terminal users. Forecasts are not based on historical data but do include seasonality concerns. The model is then iterated over the forecast duration on a periodic basis which is monthly. The forecast is maintained in a BEST/1 command list which simplifies adjustments and multiple iterations.

Two forms of the model are executed. The first is an unconstrained version with all possible I/O required, and any additional processor upgrades necessary to maintain response time. All workloads are kept during the iterations. This provides information with regards to potential constraints due to the execution of the existing total workload (IMS and batch). Preparation for this version may require several iterations of the model prior to the full blown unconstrained version to identify a potential iteration (month) which may need adjustment to maintain the unconstrained goal.

A second version of the model is executed using the current processor model to determine workload break points. I/O upgrades that were needed in the unconstrained version are maintained. This version is used to determine if the IMS response time exceeds the acceptable limits, what effects removing workloads are to the forecast, and how and when other workloads on the processor degrade performance.

Upgrades are projected for the quarter in which the model iteration exceeds requirements. Based on the results of the second version of the model, recommendations are then presented to management concerning processor upgrades, workload shifts between processors, and warnings concerning service level impacts.

The results of the constrained model, the second version, are kept in the generated BEST/1 SAS file and forms the basis for the forecasted/planned IPUs that will be used in the analysis of variance procedure.

Figure 5. Workload for Representative Hour

ANALYSIS OF VARIANCE USING INFORMATION PLANNING UNITS

An Information Planning Unit (IPU), as defined by Vincent, is the total system resource required to process each transaction. In the following implementation, this includes only the transaction volume and the CPU time adjusted by the capture ratio for the representative hour. The forecasted/planned IPU is calculated from the model iteration. The *Plan Unit* is the forecasted transaction volume (arrival rate) for a particular iteration of the model. The *Plan IPU* is the *Plan Unit* times the average CPU time for a transaction taken from the baseline model or the model iteration if a forecast adjustment was made during the iteration. An average *Plan IPU* is then simply the expected average CPU time per transaction.

The *Actual IPU* is taken from the observed IMS application performance for the day and hour chosen by the representative hour method described previously. The *Actual Unit* is the current transaction volume and the *Actual IPU* is the *Actual Unit* times the current average CPU per transaction for the application or overall IMS Subsystem. Since the forecast is based on monthly intervals the analysis of Actual to Planned variances is on a monthly basis.

Three levels of analysis are undertaken: Volume Variance, Transaction Mix Variance, and a Rate Variance. The Volume Variance is that which occurs when the transaction volume for the IMS Subsystem is greater or less than that which was forecasted. The Mix Variance results when the application mix within the IMS Subsystem differs from that forecasted and again uses the total IMS data values. In this case the overall average CPU time is used in calculating the IPU values for Planned and Actual. Both of these variances are related to the user requests for service and are stated in Figure 6.

The third variance is reflective of the resource usage required by the IMS application. Unlike the previous variances the Rate Variance is influenced by system capacity, performance, or inefficient transaction design. The Rate Variance for this implementation occurs when the *Actual IPU* varies from the *Planned IPU* on an application basis within the IMS Subsystem. This then is the summation of the primary two application IPU differences multiplied by the observed *Actual Units* for the applications and the IPU for all the other IMS workloads multiplied by the total *Actual Units* for the other workloads within the IMSID. This is expressed as the Rate Variance in Figure 6.

The TOTAL Variance for the IMS system is the sum of the Volume, Mix, and Rate variances. For reporting purposes the variances are expressed as the percent difference of the Actual and Planned IPU performance.

PRACTICAL APPLICATION USING AN ACTUAL CASE

The following demonstration of variance analysis of an IMS Subsystem is based on comparing a forecast of the Subsystem done in November of 1986 to actual resources consumed in April 1987. Because the forecast iterations are based on monthly intervals, the verification of the forecast begins with the selection of the representative peak processing hour for the month of April. In a previous section of this paper it was proved that April 28, 1987 from 10:00 to 11:00 was a representative peak hour for the month. The remainder of this section will calculate the variance of the forecasted and actual resources consumed and how much of that can be attributed to Transaction Volume, Transaction Mix, and the CPU rate per transaction.

In order to determine the workload variance the necessary information is first written down on a worksheet (Attachment A) and is then entered into a SAS program as Macros (Attachment B). This program calculates the total variance and apportions the variance of the three variables, transaction volume, transaction mix, and transaction CPU usage or rate per transaction Figure 7.

The first item to be filled out on the worksheet is **_PLANIPU.** This is the Planned Information Planning Units. In this case the CPU utilization of the IMS Subsystem from the BEST/1 forecast was converted into seconds. For April of 1987 our forecast showed the IMS Subsystem would consume 3,188.9 CPU seconds during a representative peak hour.

_PLANUNI is the forecasted transaction arrival rate also obtained from the BEST/1 model for April 1987. The forecast showed that the transaction volume of a representative peak hour would be 92,880.

_ACTLUNI is the actual transaction volume from the selected representative peak hour during April 1987 obtained from the Application Usage Summary report (Figure 4). The actual transaction volume was 92,693.

_ACT1UNI is the actual transaction volume of the primary workload of the IMS Subsystem for April 1987 obtained from the Application Usage Summary report (Figure 4). Since one workload is dominant in terms of transaction volume and CPU usage, _ACT2UNI was set at zero. The actual transaction volume for the primary workload was 78,652.

$$\text{Volume Variance} = \frac{\text{Plan IPU}}{\text{Plan Unit}} \times (\text{Actual Unit} - \text{Plan Unit})$$

$$\text{Mix Variance} = \left(\frac{\text{Actual IPU}}{\text{Actual Unit}} - \frac{\text{Plan IPU}}{\text{Plan Unit}}\right) \times (\text{Actual Unit})$$

$$\text{Rate Variance} = \text{SUM}((\text{ACTIPU1} - \text{PLNIPU1}) \times (\text{Actual Units 1}), (\text{ACTIPU2} - \text{PLNIPU2}) \times (\text{Actual Units 2}), (\text{ACTIPUn} - \text{PLNIPUn}) \times (\text{Actual Units n}))$$

Figure 6. Variance Equations for IPUs

_ACT1IPU is the actual primary workload CPU time per transaction from the selected representative peak hour expressed in milliseconds. This is calculated by dividing the primary workload milliseconds per transaction from the Application Usage Summary report (Figure 4) by the ratio of ISYCPUTM to the adjusted workload (ADJISY) performance group time (Figure 5). The ratio for the selected representative peak hour was 51.61%. This means that the ISYCPUTM from the MICS IMS database for this selected representative peak hour was 51.61% of the IMS performance groups PGACPUTM adjusted with a capture ratio (ADJPGATM, CRATIO). The actual primary workload CPU time per transaction for April 1987 was .03918. _ACT2IPU was set at zero.

_ACTXIPU is the actual total non-primary workload CPU time in milliseconds from the selected representative peak hour. The method for calculating this value is the same as for _ACT1IPU with the exception of subtracting out the primary workload(s) CPU time. This number is then divided by the number of non-primary workload transactions. In our example the system total milliseconds per transaction from the Application Usage Summary report was divided by 51.61% (ADJISY). This value was multiplied by the total number of transactions to give a total CPU time of the IMS Subsystem. Next, the _ACT1IPU was multiplied by _ACT1UNI. This CPU time which represents the primary workload was then subtracted from the total CPU time for the IMS Subsystem. The remaining non-primary workload CPU time was then divided by the non-primary transactions, _ACTLUNI minus _ACT1UNI. The actual non-primary workload CPU time per transaction for April 1987 was .01515.

_PLN1IPU is the planned primary workload CPU time in milliseconds per transaction. This number is derived by multiplying _PLANIPU by the percentage of total IMS Subsystem CPU time the primary workload is expected to be at this point of the forecast. This information is extrapolated from the selected hour used in the baseline model plus or minus any adjustments made over the forecast. Since there is only one primary workload, _PLN2IPU is zero. The planned primary workload CPU time per transaction for April 1987 is .0379 milliseconds.

_PLNXIPU is the planned non-primary workload CPU time per transaction in milliseconds. It is calculated the same way as _PLN1IPU but for non-primary workload transactions only. The planned non-primary workload CPU time per transaction for April 1987 is .0137.

The output from the program used to determine the workload variance of the IMS Subsystem for April 1987 is shown on Attachment A. The total variance of Actual IPUs to Planned IPU was 3.3%. Of this total variance, -0.2% was attributable to a slightly lower actual transaction volume than was planned. Transaction Mix accounted for -0.3%, and CPU usage or rate per transaction accounted for 3.8%, due to a higher actual CPU rate per transaction versus the planned CPU rate per transaction for both the primary and non-primary workloads. All initial conclusions and recommendations made at the time of the original forecast for this particular IMS Subsystem would appear to still be valid.

The final verification of that is dependent on whether or not service levels are being met. In this case, response time is synonymous with service levels. If the forecasted response time at a particular model iteration is at or under the service level agreement and the actual response time meets accepted service levels then the original forecast remains valid.

CORRELATION OF MODEL TIMEFRAME SELECTION AND VERIFICATION

Even though the forecast is currently done on a periodic basis the entire process of model timeframe selection and forecast verification is a continual process. Capacity Planning verifies the IMS forecasts on a monthly basis. The same process that was used to select the timeframe for the baseline model is used to verify the forecast. At a future date, when it is time to generate a new forecast, the verification process provides the analyst with the current baseline.

Figure 7. IPU calculation results

DB2 IPU DEVELOPMENT

Development of IPUs for a DB2 Subsystem is currently in progress. DB2 is operated under TSO/QMF with the installation of an IMS interface expected in the near future. The DB2 Subsystem shares the processor with various other workloads. It is not the heaviest workload on the processor, but due to the user support functions, it is the most critical with regards to the need for sufficient processing resources. The DB2 Subsystem does not maintain any consistency in the number of queries, processor utilization, table processing counts, etc., and is continuously growing in all of the above areas.

As can be expected from this, the peak to average ratios for query processing form a wide range. These ratios are tracked using MICS for both performance group RMF statistics, (SCPPGA file) and the DB2 SMF log facilities (DB2DSY file). The later is used to define an average query per thread using the CPU time, and the table access counts (select, fetch, sequential prefetch, update, insert and delete). Since threads can be reused, they are not indicative of arrival rates and are used only as additional information for selecting the DB2 representative hour.

Selection of the model timeframe (day and hour) for this processor is based on the ninetieth percentile query estimate using the query termination plus abort count from the MICS DSY file (DSYTERM + DSYABORT). Not all DB2/TSO users are in individual RMF performance groups or reporting groups, which requires that the traditional TSO users to be modeled as part of the primary workload. The actual day and hour for the model timeframe capture is selected using the previously defined method for the IMS system.

The baseline model combines the performance groups for TSO, DB2 TSO users, and the DB2 system address spaces into one workload, batch into another, etc. Workload growths are gathered for individual DB2 applications, applied to the forecast, and modeled as a TP workload using the RMF ended transactions (PGATTX) as the arrival rate.

The average response time is used simply as a guideline in the current model iteration evaluations. The response times range from several seconds to several minutes due to table sizes up to several hundred thousands and is therefore not a modeling criteria. Again the output of the BEST/1 model is saved in a SAS file for variance comparison of forecasted arrivals.

The IPUs for the DB2 workload consist of the ended transaction counts (PGATTX) and the average CPU seconds per transaction (PGACPUTM) as reported by RMF and captured in the baseline model. The Volume Variance, Mix Variance, and Rate Variance are calculated and evaluated using the same method previously defined, with exception of using the ISYCPUTM to PGACPUTM ratio. This ratio has not yet been validated for DB2 as most of the processing is charged to the user address space. The workload time (PGACPUTM) to the total PGACPUTM is used. In this case, the primary workload is defined as the TSO system (both DB2 and non-DB2 users). The secondary workload is the TSO/DB2 only performance group. All other performance groups, including the DB2 system address space, and the IRLM are combined in the last IPU grouping. The analysis proceeds as in the above IMS example. The key is in the definition of the primary/secondary workloads.

The drawback of the ended transactions from RMF is that it does not directly relate a transaction to the SQL query. In forecast data gathering, the users issue estimates on the basis of the latter.

A further exploration is being made to also include the average table I/O count as part of the definition. The IPU would then be the transaction count times the average CPU seconds plus the transaction count times the average table access count rounded to housands. The difficulty in this is defining the average table access count per workload. Therefore an overall average per thread count is used and applied to each workload in the Rate variance.

Another approach is to use the estimated I/O count from the pages read (RIO) and pages updated (WIO) calculations using the DB2 buffer statistics (in the MICS DSD file) averaged by the number of queries (DSYTERM + DSYABORT).

CONCLUSION

This paper has demonstrated the following: 1) a methodology for selecting a representative timeframe to model an online transaction processing system such as IMS. 2) An overview of the modeling process. 3) An overview of Information Planning Units (IPUs) and analysis of variance of workloads as introduced by David Vincent. 4) A practical application of IPUs and analysis of variance of an IMS workload. 5) Correlation of the model timeframe selection and forecast verification process. 6) Application of IPUs and analysis of variance of a DB2 workload.

This whole exercise of workload variance analysis is to determine whether or not a workload is consuming resources according to expectations. If it is not, then this technique can assist the capacity planner in determining what caused the variance and how this variance is impacting the forecast and ultimately the end user.

Disk Cache Performance Modeling

Michael A. Salsburg
UNISYS

ABSTRACT

In order to reduce the performance bottleneck caused by physical disk accesses, a large global disk cache has been implemented. During the design phase of this product, I/O workloads were studied and modeled. This paper describes the disk I/O subsystem, the I/O model and the results of the modeling, emphasizing the benefits of this style of disk caching.

Introduction

The end-user of a computer experiences the effects of computer performance as the delay between commands and responses. The delay between these events can be broken into transmission delay, processor delay and I/O access delay. As processor speeds increase, and line costs decrease, the I/O access delay is becoming a dominant factor in computer performance evaluation.

This paper presents a model of the I/O subsystem for the UNISYS A series systems. Since little has been published in this area, a description of the I/O subsystem's components is included. A trace-driven simulation model has been developed to observe the effects of various performance parameters using customer workload traces. A new feature, the Software Disk Cache Module, has been modeled and studied over the past two years. It significantly reduces the I/O bottleneck. Results from experiments in both modeling and real systems are included.

1. Workload - The Nature of Disk I/Os

Disk I/Os are requested by application processes on the host. Typically, these processes wait until the I/O is completed before continuing. As processor speeds continue to increase, the actual elapsed time, or "wall clock" time, for an application depends more heavily on the mechanical delays that are inherent in the disk subsystem. The events that contribute to the delay are effectively the same for disk READs (transfer from the spindle to main memory) and WRITEs (transfer from main memory to the spindle).

The arrival of these I/O requests is the workload of the disk subsystem. Traditionally, it has been assumed that these arrivals are a Poisson process. This assumption is used for two reasons. First, it reflects a high degree of conformity to actual arrival patterns when many independent processes are requesting service from a finite number of disks. The second reason is the tractability of mathematical models. Figure 1 shows the percent of I/O processing that was offered for a specific disk in one of the typical workloads studied.

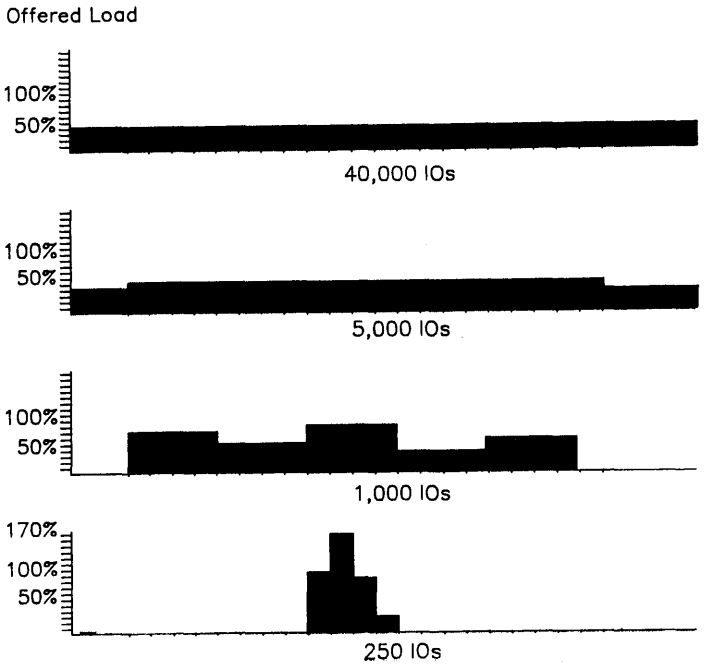

Figure 1

Chart (a) shows that, for a 40,000 I/O batch, about 40% of the capacity of the unit was requested. Chart (b) shows the offered load for a 5,000 I/O subset of that batch. Inspecting this batch separately shows that about 50% of the unit's capacity was requested, while other batches were lower. This batch is again subdivided in chart (c). Here, the offered load is analyzed as 1,000 I/O batches. In chart (d), the intervals of 250 I/O batches are displayed. Notice that one of the batches indicate an offered load of over 170% of the unit's capacity. Requests of over 100% indicates queueing between batches.

This level of variability is indicative of the Poisson process. There are two properties of I/O requests that do not fit the model of the Poisson process. First, I/O requests generally appear as bulk arrivals. In fact, the variability of actual workloads appears to be much higher than the Poisson process. Secondly, the arrivals are not independent. The 170% offered load was primarily generated from one application process. The determination of a more realistic description of the arrival process of I/Os may reveal better and more accurate modeling in the future.

2. The I/O Subsystem

This section will describe the events that occur in processing an I/O request. It includes a description of the disk caching that is used to reduce the delay an application process encounters when an I/O request is made.

Figure 2 shows where the Input Output Subsystem Module (IOSM) is positioned in the I/O process. Section 2.2 contains a discussion of the Cache Submodel. Section 2.1 discusses the IOSM submodel.

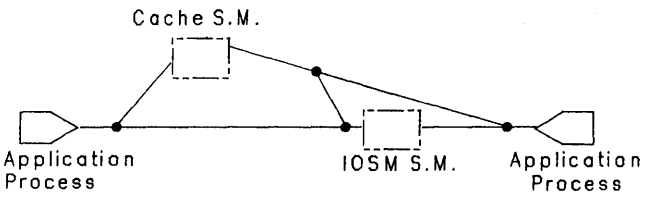

Figure 2

2.1 Standard (non Cached) I/O Request

Figure 3 displays a simple picture of the key elements in the I/O subsystem. In UNISYS A series machines, an I/O request is sent through the Message Level Interface (MLI) to the Data Link Processor (DLP) to the unit controller and finally to the unit. Many DLPs are connected to the host on a single MLI. Many units may be connected to a host through a single DLP and controller. For all practical purposes, the DLP and controller can be thought of as a single entity, since one does not process without the other. The two names will be used interchangeably.

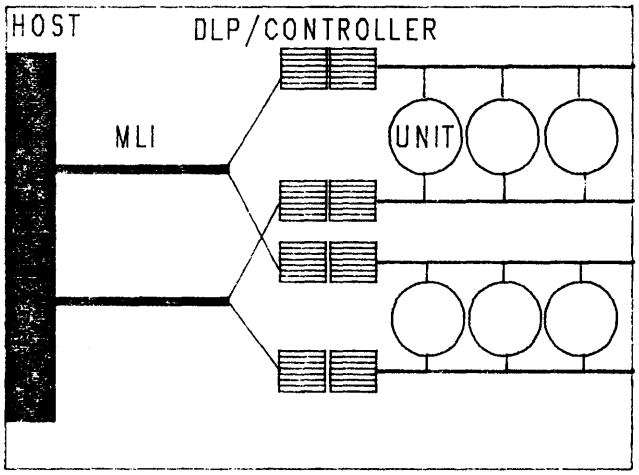

Figure 3

Figure 4 presents the detail of the IOSM submodel. The flow is from left to right. It is assumed in this example that a READ request has been issued to a unit. When an I/O for a particular unit becomes active, all future I/Os for the active unit are queued until that I/O completes.

The first event in the submodel is the acquisition of the Unit in the Unit Submodel (S.M.). Next, the command for the I/O must be sent through the MLI to the controller via the DLP. Once the command enques in the DLP, it is processed for **D1** milliseconds. If there is a need to move the unit's arm to the requested cylinder, a seek delay occurs for **D2** milliseconds. Once the seek delay completes, the controller is acquired again. The controller is not released until the final data

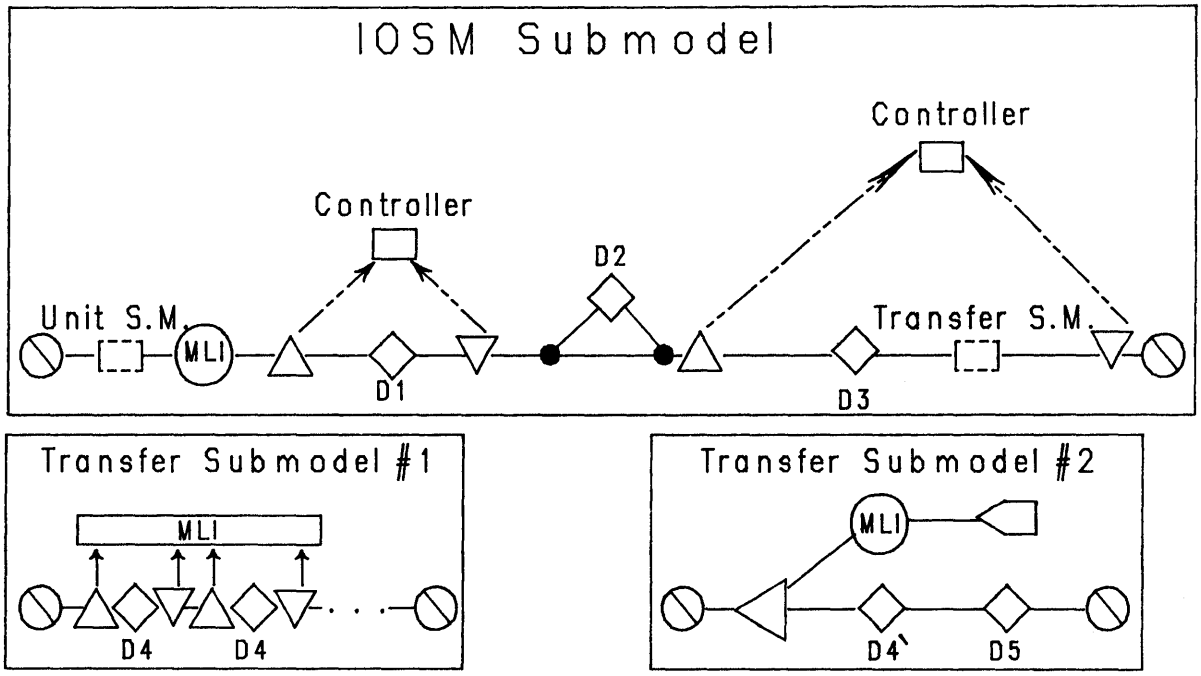

Figure 4

transfer completes. During this period, there is a delay for additional controller time and latency (D3). Once the data revolves under the READ/WRITE head, the transfer of data occurs. Two submodels are shown for this transfer. They will be discussed in section 4.1. The I/O completes when the data is successfully transferred.

Notice that the controller is busy during the latency phase. IBM compatible systems use a different scheme, called Rotational Position Sensing (RPS). See [2],[3] for a discussion of RPS modeling.

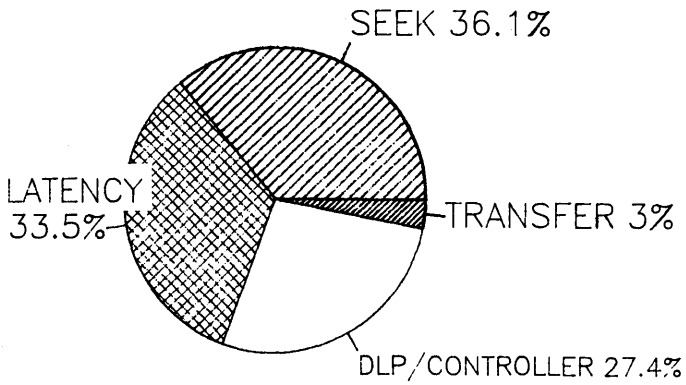

Figure 5

Figure 5 compares the amount of delay in seek time, latency, transfer and DLP/Controller processing for a thin film disk (Memorex 3680). Notice that the majority of the delay is devoted to setting up the transfer, while the transfer time is relatively negligible (3%). Disk caching has been introduced to reduce most of these delays.

2.2 Cache I/O Requests

A large software disk cache has been implemented for A12 and A15 UNISYS systems. Disk caching has been used successfully in the past to reduce I/O delays. The memory for software disk cache resides in the host's system memory. Many of the current disk caches have been implemented by introducing memory into the controllers and caching at the controller level. By using main memory, all disk units connected to the host may share the same cache. The size of the cache may be quite large (144 MBytes). The following is a brief description of the disk caching scheme.

In Figure 2, the placement of the disk cache submodel is shown. If a unit has been assigned the caching attribute, each I/O for that unit is

inspected by the cache algorithm before it enters the unit queue. When a READ request is found, the address of the disk data is inspected. If this address is not currently in the cache (cache 'miss'), the I/O command is replaced by a request for the entire track of disk in which the data resides. This request is then passed to the IOSM. The full track is read into the cache and tables are updated accordingly. If a READ request arrives for data already in cache (a cache 'hit'), the data is transferred from the cache memory to the application's I/O buffer without requiring IOSM resources.

For WRITE requests, all WRITEs are written to the physical medium. If a WRITE request is made for data in cache, the cache data is updated in addition to the physical update.

Memory is managed using a least recently used (LRU) algorithm. When memory is needed to hold a new disk track, the least recently used track is discarded. For a full description of caching and various algorithms, refer to [4]. In the terminology of Smith's paper, the cache algorithm is a write-through, write-update cache.

The performance issues of caching involve the effects of full-track transfers on the system, the trade-off of slower full-track READs (cache miss) for faster memory-to-memory transfers (cache hits) and the effects of cache size. These will all be presented in later sections. The next section is used to present the model that was developed to explore these issues.

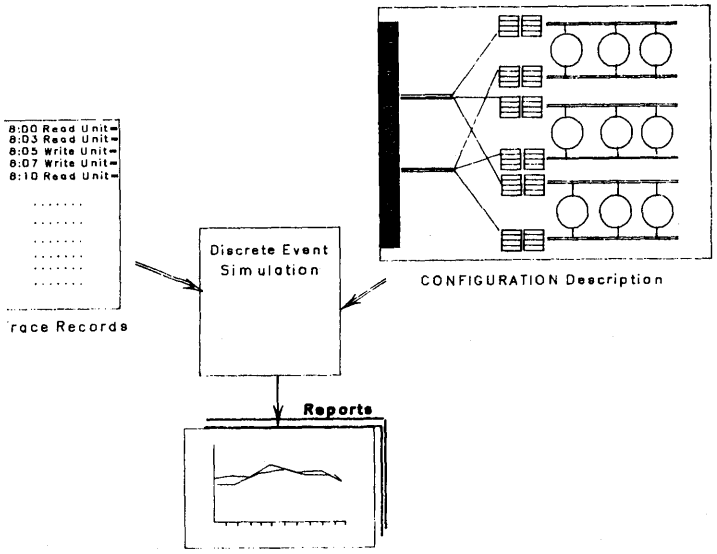

Figure 6

3. The IOSM Model

The performance of the I/O subsystem was studied using a trace-driven discrete event simulation model. It should be mentioned that, although many simulations involve Monte-Carlo methods, the majority of the events were deterministic. The simulator was used to evaluate the complex distributions and interplay that is difficult to predict using mathematical modeling.

Figure 6 presents a simple diagram of the simulation system. Traces of customer workloads were used to generate the arrival times and nature of the disk I/Os. A configuration file was used to describe the connectivity of the system. In this way, the simulation could be easily rerun and compared using alternate configurations. For seek I/Os, a mathematical model was used to produce seek delay times. The latency was calculated directly using the position of the data and the simulation time. DLP/controller delay times were determined from benchmarks. I/O performance metrics are calculated for batches of I/Os. Although the batch size is a parameter, the size was kept at 1000 I/O batches for consistency throughout the project. Autocorrelation of consecutive I/O delays is negligible beyond groups of 20.

Validation was an iterative project. As understanding of the system increased, re-validation helped identify key parameters of the system. The measured elapsed times for the I/Os were included in the trace data. One goal of the modeling project was to discover the minimum parameters necessary to accurately account I/O delay. The model appears to generate similar delays when compared to the workload traces. For non-seek I/Os, the average error was 3% of the average delay. For seeks the error was 4% of the actual average delay.

The caching algorithms were implemented using library calls from the simulator. The library manages the LRU data structures. The consistency of the LRU algorithm of the model is guaranteed to reflect the actual cache algorithm because the implementors of the software and the modelers shared the same algorithms.

4. Model Results

Using the workload description, the basic components of the I/O subsystem and the model, many scenarios were examined. The following subssections provide results from a few of the experiments.

4.1 MLI Modeling

In developing a simulation model, the question of granularity must be addressed. If the model accounts for short, frequent events (on the level of microseconds), while other less frequent events occur at a higher granularity, processor requirements are unreasonably high. The transfer of full track data across the MLI needed to be studied. It was decided to implement the actual buffering and bursting of data across the 8 megabyte/second MLI. Figure 4 shows the Transfer submodel #1. Since many DLPs share the MLI, the DLP connects and disconnects many times to transfer the data. Queueing will occur when a connection is requested; however data is being transferred from a real-time, spinning disk. If the queue size is too high, the unit is forced to disconnect from the DLP and revolve back to the remainder of the data (disk slip). This disk slip adds an additional 16.67 milliseconds to the I/O delay.

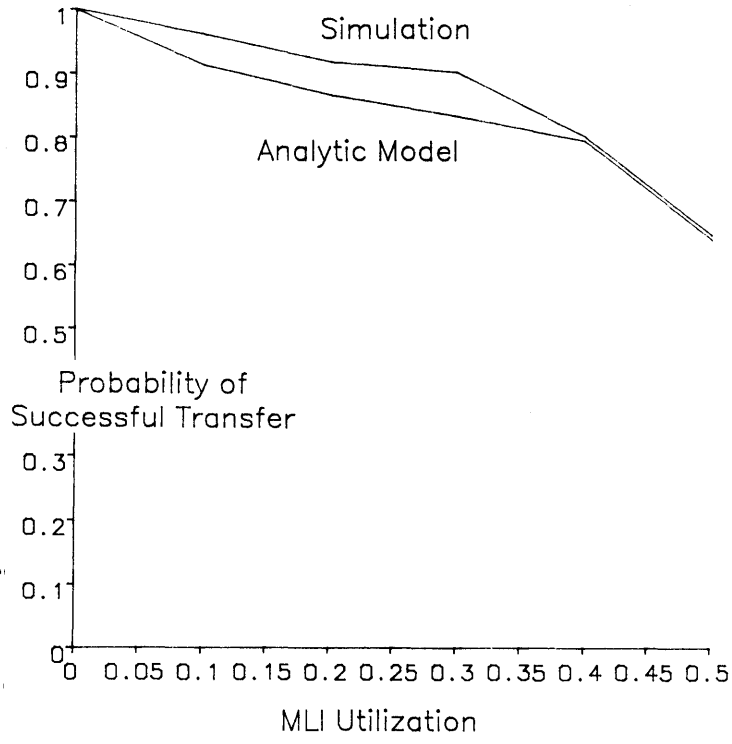

Figure 7

A mathematical model of the probability of disk slip was developed and compared to the simulation. The purpose was to replace the simulation events of MLI transfer by a simple delay. In Figure 4, Transfer Submodel #2, The multiple connections and delays are replaced by a single delay **D4** with an additional, calculated delay for disk slips. This alternate submodel reduced the processor requirements by over an order of magnitude.

Figure 7 resents the validation of this approach. Notice that at 50% MLI utilization, 35% of all I/Os will have an additional delay of 16.67 milliseconds. In all extant systems, the MLI utilization is usually under 0.8 megabytes/second. A problem will occur if a Line Expansion Module (LEM) is used. This module is often used to cross-connect DLPs for redundancy. Unfortunately, the LEM reduces the effective bandpass of the MLI by one-half, which means the utilization is doubled on these systems. MLI utilization must be carefully considered when cached disks are connected using LEMS.

The analytic formula for predicting the probability of a disk slip is:

$$P(\text{disk slip}) = 1-(1-p^{n})^{m}$$

The device utilization is **p**. The power of **n** is the minimum number of buffers in service and queued that will cause a disk slip (assumed to be 5.5 in this study). The power of **m** is the total number of times the DLP will attempt connection to the MLI to transfer a full track of data (assumed to be 20).

Due to the accuracy of this analytic model, a portion of the simulation could be replaced by simple arithmetic operations. This reduction made the modeling of the entire IOSM feasible.

4.2 Profile of Workloads under Test

The remainder of this section will discuss various aspects of disk cache performance. Throughout this discussion, a single workload will be cited. It would be preferrable to display multiple examples, but there is a limit to the size of this paper. The workload is a trace of a customer sites'

online system. Whenever performance is discussed, the usual caveat of "your mileage may vary" must be emphasized. This section is also intended to present the small number of parameters that need to be considered in evaluating any workload.

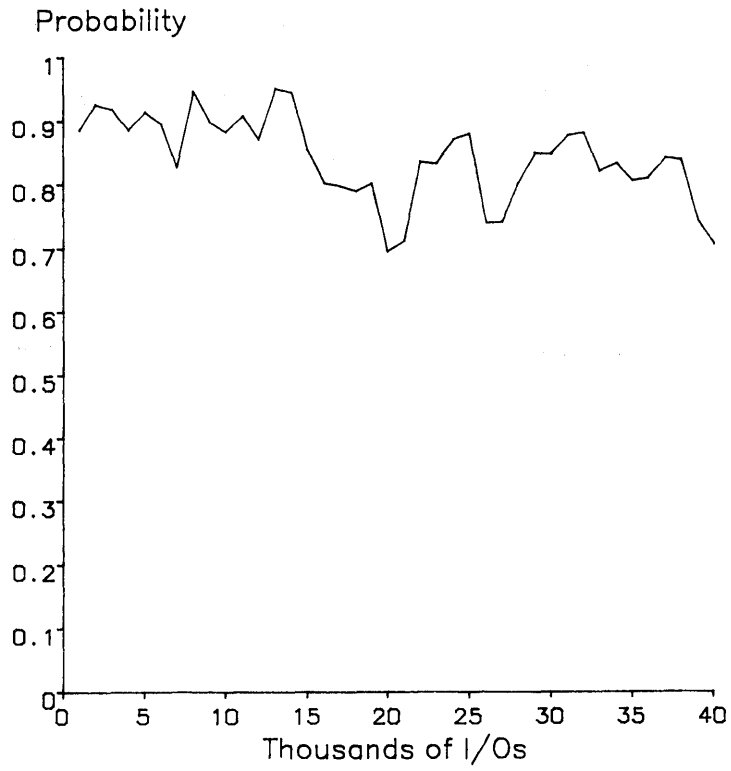

Figure 8

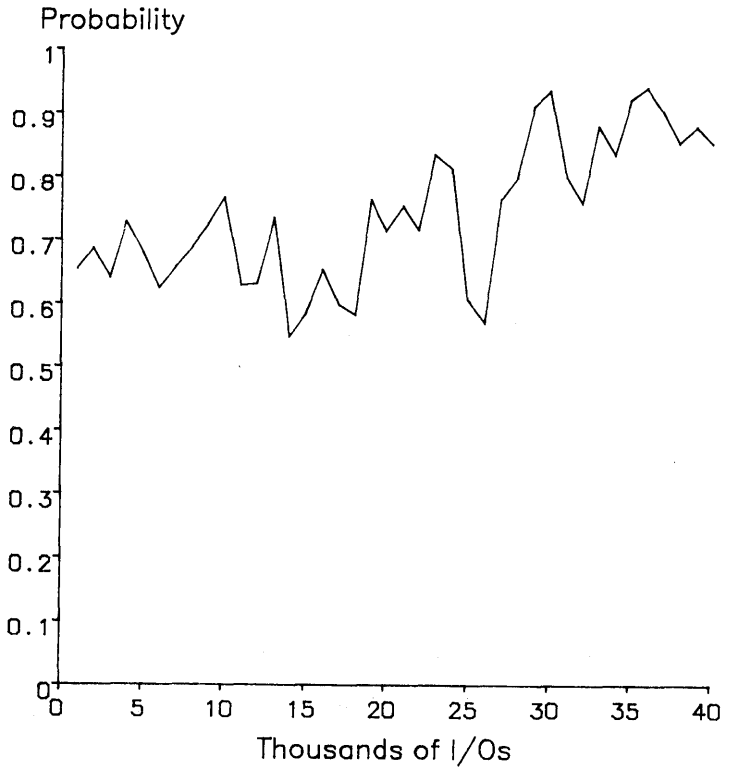

Figure 9

4.3 Parameters of Cache Performance

Figures 8 and 9 present the most important characteristics effecting cache performance. In Figure 8, each batch of 1,000 I/Os was assigned a probability of having a READ request. The other metric that is necessary is the probability of the READ being a cache 'hit'. This evaluation requires processing the I/O trace through the LRU algorithm. The probability is affected by the cache size. The smaller the cache size, the less tracks in cache and the lower the probability of finding the data resident. Figure 9 shows the probability of a READ 'hit' given a cache size of 100 megabytes.

The basic philosophy of global disk cache is that the caching algorithms need not be too elaborate if the memory size is sufficient. Since system memory is capable of growing to 192 megabytes on an A15 system, 100 megabyte caches do not seem unreasonable. Figure 10 shows how the overall cache hit probability changes as a function of memory size. This graph is typically displayed using a logarithmic scale for memory size, which displays a steeper curve. However, most people involved in the cost of memory do not consider it logarithmic, therefore, the linear scale is used.

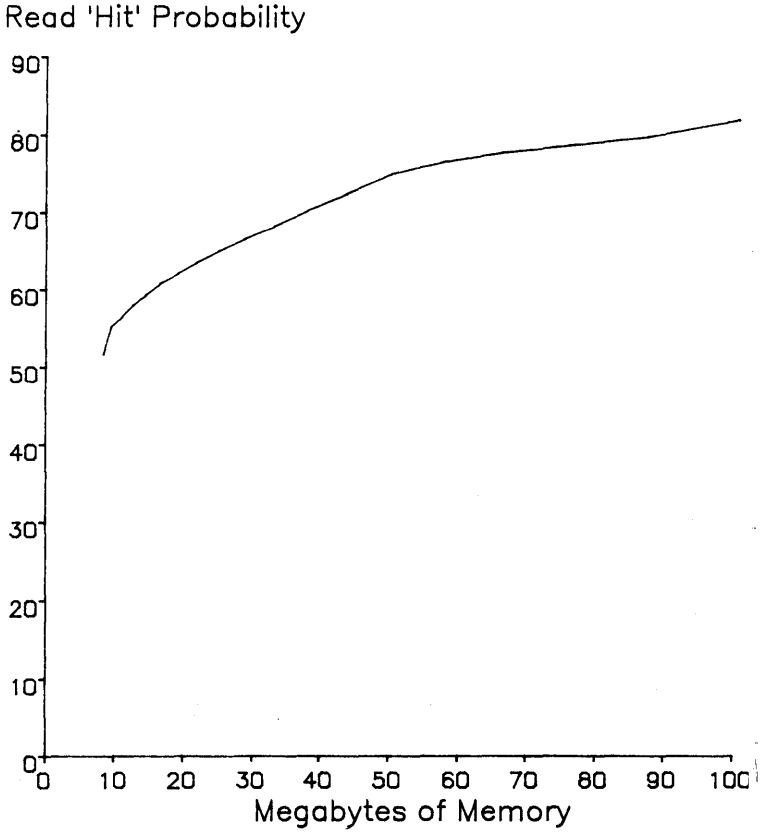

Figure 10

4.4 I/O Service Improvement

Many workload traces were tested on the cache simulation model. One method of comparing cached vs. non cached performance is by the reduction of I/O service time. The I/O service time is defined as the elapsed time that the I/O is active. From the application process view, it is the I/O delay minus the unit queueing delay. The cache improvement (CI) is the ratio of the non-cached service time divided by the cached service time. As the probability of READs increase and/or the probability of cache 'hit's increases, the cache improvement metric increases. Figure 11 shows the cache improvement metric calculated for each 1,000 I/Os of the workload. Workloads with consistent 90% cache hit and READ probabilities show I/O delay reduction to one-fifth of the non cached delay.

Notice that the improvement does not go below one. This would indicate that the cache was slowing down the I/O delays. Adverse effects of controller cache has been reported in the literature. In order for controller caches to remain effective, the rule-of-thumb is to keep the READ probability and the READ 'hit' probability above 70%. If these rules are not followed, the excessive controller utilization, due to cache management, will cause delays which will elongate the I/O delay times for all units connected to the controller [1]. The cache is extremely resilient to these factors. It will be shown that a low probability of READs may have no adverse effect on cache performance. Furthermore, READ 'hit' probabilities can drop below 50% without causing I/O performance degradation.

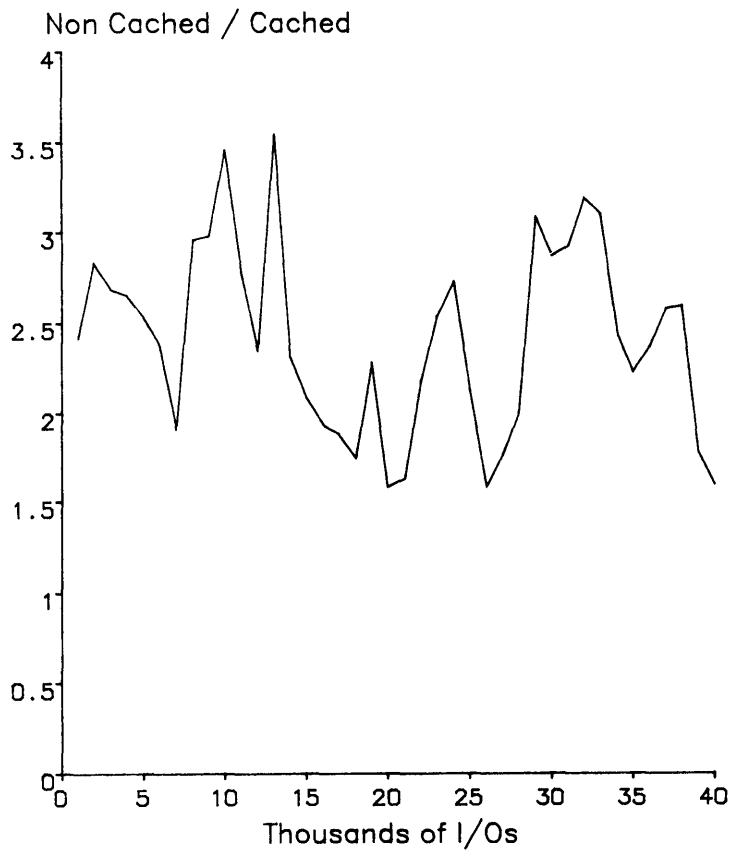

Figure 11

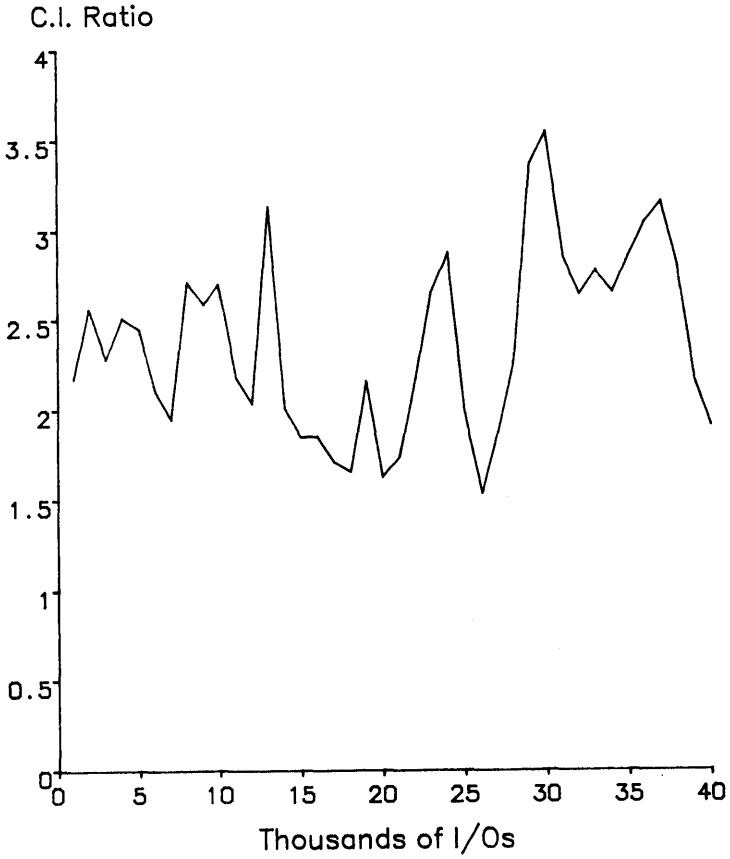

Figure 12

4.5 A Model of Cache Improvement

It would be extremely useful to have a simple algorithm to compute the cache improvement, without the necessary simulation requirements. Along with the original research into global memory disk cache schemes, Tim Fender of UNISYS developed a simple formula for predicting the cache improvement ratio:

$$CI = 1/(C_1 + 1 - P_R(1 - C_2 * (1 - P_H)))$$

where:

P_R = probability of READs
P_H = probability of READ 'hit'
C_1 = average increase of processor time
C_2 = average ratio of service for full track I/O vs "regular" I/O

Figure 12 shows the CI as calculated with the above formula. The constant C_1 represents the additional CPU resources necessary to process cache misses, averaged over all of the I/Os. For this workload, .02 (milliseconds) was used. It should be noted that, when a cache 'hit' occurs, the processor utilization is less than that of an ordinary READ I/O. The constant C_2 is used to represent the additional delay for a full track transfer over the delay for an 'average' I/O. Since the transfer time is not the majority of the I/O delay, and the average transfer size was 2800 bytes, C_2 is set at 1.5. The formula underestimates the actual cache improvement; this is due to the controller queueing delay improvement. Since the cache has reduced the utilization of the controllers, the controller queueing has been reduced, thus lowering the delay time for an active I/O. The effects and distribution of controller queueing are now under study.

Using this lower estimate of cache improvement, examine the formula for $\%_R = 0$. If the system encounters all WRITE I/Os, the overall cache improvement is

$$1 / (1 + C_1).$$

For C_1 = .02, this implies a degradation of the I/O delay by 2%, due to additional processor overhead. Assuming there are READ I/Os, a degradation will not occur if

$$C_1 * (1 - P_H) < 1.$$

For C_2 = 1.5, the P_H must be above 1/3.

4.6 Elapsed Time Improvement

Although the CI metric is easy to calculate and considered a reliable indicator, the final success rests in the actual difference in elapsed times encountered when running application processes. This difference in elapsed times includes the reduction in unit queueing. Notice that WRITEs and READ 'misses' are now being processed in a system that is less utilized. Therefore, the overall unit queueing is reduced. In this way, all I/Os experience less delay if cache 'hits' are occurring. Figure 13 compares the total elapsed time for the workload. Notice the scale for Elapsed Improvement. This is the ratio of non cached I/O delay over the cached I/O delay.

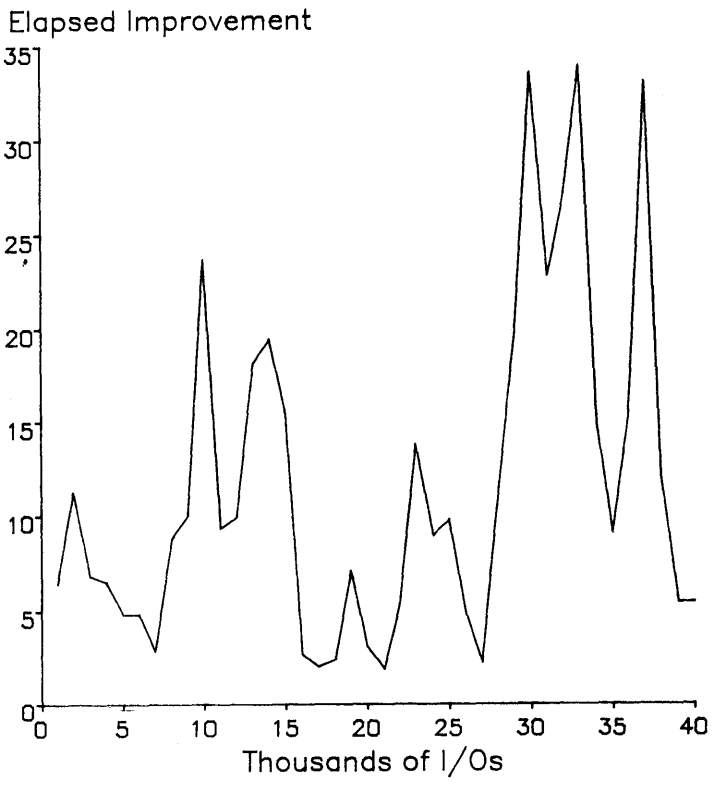

Figure 13

5.0 The Product

All of the modeling results were completed before the product was implemented. The first test site for the software was an internal system . The experience of using the product met the expectations predicted by the modeling. The CI metric has been tested with actual elapsed times reported for applications that were run with and without disk cache. Some extraordinary results were reported recently where a production system ran an overnight batch program in three of the usual eight elapsed hours. At one point, two units were each logically handling over 1500 I/Os per second. On the other hand, a site consisting of totally random update transactions showed a decrease in I/O delay ranging from 8 to 30%.

6.0 Conclusion

The nature of the UNISYS A series I/O subsystem has been presented, emphasizing the performance of the global disk cache feature. As has been shown, the benefit of the caching feature on the I/O bottleneck may vary greatly from workload to workload. Ultimately, some analysis is necessary to insure that the improvement will justify the cost. Hopefully, this paper will bring to light the main issues that are involved with this sort of analysis.

The modeling project has raised many interesting questions, such as the real nature of I/O arrivals, and the distribution of various delays throughout the subsystem. A four month benchmarking project has just been completed. The results of these experiments are the subject of a future paper. The understanding and configuration of large disk subsystems grows in importance as processor times continue to shrink.

6.0 Acknowledgments

I would like to emphasize that this work was built on the strong foundation of Tim Fender's research and preliminary modeling. I would like to thank him for his encouragement and patience. Technical assistance was provided by the principal software disk cache implementor, Will Stratton.

A Method For Reporting Cashed I/O Subsystem Performance

Nancy Nearing
The Washington Consulting Group

ABSTRACT

Recently, at a client site, we developed the capacity to monitor cached I/O subsystem performance for more than two hundred DASD volumes capable of being cached. The volumes were configured on approximately 35 strings with NAS model 23 cache controllers, shared among four Amdahl 5870 attached processors, three of which were running MVS/XA, and one of which was running MVS/370. Each string usually contained at least one cached volume, but the configuration was prone to frequent changes.

Using the SMF 244 and 245 records produced by the RMF cache reporter, combined with standard RMF data on response time and start I/O requests, we developed a series of SAS programs to depict cache performance characteristics for the entire configuration. These reports show the additional connect time, caused by cache activity, which is invisible to RMF. This additional connect time is a symptom of the increased controller utilization caused by staging operations. It can cause increased RPS reconnect delays and overall I/O performance degradation; therefore, it should be watched carefully.

1. Background:

The basic measure of cached DASD performance is response time. If cached volumes show significant response time improvements over non-cached volumes, then cache is operating satisfactorily, and there is no need for tuning [1]. However, if the response time improvement is not as great as anticipated, some adjustment may be required. In order to adjust, or tune, the cached I/O subsystem, one needs to consolidate the "internal" cache management data with response time data.

Consolidated cache performance data, however, is difficult to come by. Since cache management functions are "invisible" to host computer software monitors like RMF and SMF, the performance analyst has no easy way of measuring cached DASD performance. The IBM 3380 storage director maintains cache management data which is used by the IBM Cache RMF Reporter to produce a voluminous, detailed report of cache performance indicators, but response time is not one of them. The report could be compared to a response time report to provide a complete picture of performance.

This is a cumbersome process at best; witness the discussion of cache controller tuning in [4]. The Cache RMF Reporter was used to provide cache management data, Omegamon was used on-line to check response times, and the RMF DASD Activity Report was consulted for volume activity information. This was all for tuning a single controller. The process could only become more awkward as more cached controllers are installed and need to be tuned.

There is a better way. In order to produce its reports, the Cache reporter writes the 3880 counts out to SMF user records. This paper describes how we merged the cache management data contained in the SMF user records with device activity data provided by RMF. Once the data was merged, we produced a consolidated, summarized report that is currently used for tuning an DASD installation with more than 30 cached controllers serving over 350 DASD volumes.

This paper describes our methodology for creating consolidated cache management data and producing summarized performance reports at a large site. Although we completed the project in the context of a commercial performance data base, the techniques we used and insights we gained are applicable to other situations and environments.

This paper is organized in five sections, a brief background to the problem (this section), an introduction to cache management data and terminology (which may be skipped by those familiar with the subject), our methodology for merging the data and creating the reports, and a thumbnail sketch of how to tune a cached system using the reports.

2. A General Description of Caching.

The primary objective of cached DASD is to improve I/O response time compared to conventional I/O. The cache is RAM shared by storage directors which have been modified to query the cache before initiating a disk access to retrieve a record. If a read request references a record currently located in the cache, transfer of data from the cache to the host can begin immediately, and proceed without the delays associated with conventional disk access [3].

A read request for a record located in the cache is referred to as a read hit, or a cache hit. If the record is not located in the cache, and a conventional I/O operation must be initiated, it is referred to as a read miss. Since write operations inevitably have to complete a conventional I/O, they do not benefit from caching. Therefore, write operations and read misses are collectively referred to as cache misses. [1] estimates read miss service time (which should be approximately the same as service time to a non-cached 3380) as 20.4 ms, and read hit service time as 2.8 ms - a savings of more than 17 ms.

Although a read miss does not take significantly longer to complete than a non-cached read operation, once the request is completed, the cache manager will "stage" data from disk to the cache, in hopes of preventing future misses. The staging operation ties up the device, channel, and control unit for the duration of the operation. Therefore, excessive staging causes cached controllers to be significantly busier than conventional disk controllers. The extra burden placed on cached controllers by staging activity is referred to as "cache overhead". This overhead is the biggest performance liability of caching and will produce significant RPS reconnect delays on cache misses. A saturated cache controller will cause overall subsystem performance to degrade when I/Os that must bypass the cache and perform conventional disk I/O operations encounter excessive reconnect delays. [3]

Aside from response time, which provides an indication of benefits received from caching, the most important indicator of cache performance is the amount of "invisible" controller utilization caused by staging, which can provide an indication of liabilities caused by cache. Response time data for a volume or a string can be derived from RMF. The only way to estimate how much additional con-

troller utilization is being caused by staging is to know how much offline staging activity there is. For a 3880 model 23, this data can be derived from the counts maintained by the storage controller itself.

Other major indicators of cache performance are hit percent, read hit percent, and hits per stage ratio. These measurements can all be derived from the cache management data. Hit percent is a measure of the number of operations that benefit from the cache compared to the total number of operations requested -- in other words, read hits compared to total I/O operations. Read hit percent is the comparison of read hits to total read requests. The hits per stage ratio compares the total number of read hits for the measurement interval with the total number of stages that took place. This provides an indication of how many read requests can be satisfied by each staging operation. the larger the number, the more benefit is being derived from the cache. As we noted above, when performance problems occur in a cached subsystem, they are usually associated with the extra controller load in cache due to staging activity following read misses. The hits/stage value provides a useful index of overall cache improvement vs. overhead [3].

The best guidelines for tuning a cached subsystem are obtained by measuring its performance under a variety of conditions, and noting the circumstances under which it tends to degrade. However, when this type of information is not available, one may refer to general "rules of thumb" for guidelines. Published rules of thumb suggest that an appropriate workload for caching should have at least a 70% percentage of read hits, and a 2:1 read/write ratio. [1]

3. Methodology.

RMF reports response time data that is an accurate measure of cached I/O response time as seen from the host computer. However, because the cache management functions are handled off-line, and therefore are invisible to RMF, RMF data alone is virtually useless in tuning a cached subsystem. In order to provide a complete picture of the internal workings of the cached subsystem, information about the cache management functions must be combined with the RMF data. Data from any version of RMF will provide response time information; RMF operating under MVS/XA is especially useful since it provides an additional measure of connect time which can be used to derive an indication of total control unit utilization.

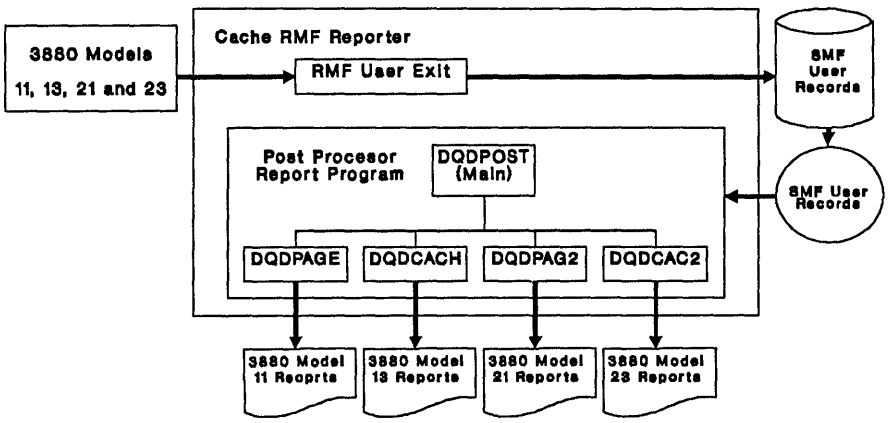
The IBM product, Cache RMF Reporter, provides information about the cache management functions. It consists of an RMF User Exit Routine, and a post-processor program. The exit routine is entered at the beginning of each RMF Monitor I session, and at the end of each RMF measurement interval [2]. Each time it runs, it issues the Access Method Services (IDCAMS) LISTDATA command, which uses the Sense subsystem Counts CCW to obtain the device counters and subsystem status for each storage controller. Since the LISTDATA command does not reset the counters, the user exit must then calculate the difference in the counts from the previous interval [1]. The results reflect all I/O activity seen by the controller over the measurement interval, and they, along with the subsystem status fields, are written to the System Management Facilities (SMF) dataset as user records. Note that the user exit does not calculate any ratios or percentages; these statistics are all derived by the post-processor program. The user exit will write a record of one type for each 3880 model 11 or 21 it encounters, and another for each 3880 model 13 or 23. The record types are specified by the user when the cache reporter is installed, and can be anything from type 128 to type 255, inclusive. The defaults are 244 for a model 11 or 21, and 245 for a model 13 or 23 [2]. The user record formats for the 3880 models 13 and 23 are included as an Appendix.

The post-processor program consists of a main routine, which reads the SMF records, and four subroutines, one for each 3880 model (11, 13, 21 and 23) recognized by the cache reporter. The subroutines calculate usage statistics, such as hit ratios and read/write ratios, from the records read by the main routine, and then generate the reports for each device [2]. The entire Cache RMF Reporter structure is illustrated in figure 1.

The Cache RMF Reporter post processor reports contain data solely from the storage controllers, and do not provide response time data as viewed from the host processor. In addition, since no data is provided on volumes brought up offline to the cache, the reports cannot show data for an entire subsystem unless all its volumes were cached over the reporting interval.

In order to provide complete information about the cached subsystems, we have substituted two SAS programs for the post- processor program. The first program is a daily SAS routine which calculates usage statistics, formats the data into two files. The first file

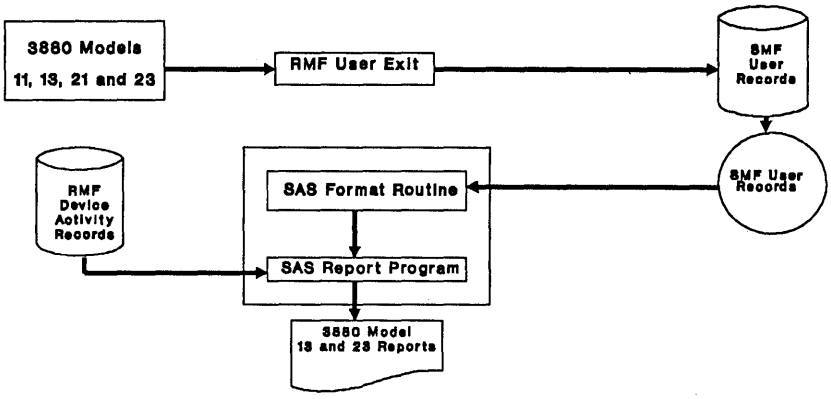
Figure 1. Overview of the Cache RMF Reporter



Adapted from the Cache RMF Reporter Program Description/Operation Manual

maintains data pertaining to an individual volume, and the second maintains data pertaining to an entire string. The second program is a report program, which merges the user record data by date, hour, and volume ID with RMF data on device activity, providing data for both cached and non-cached volumes. The cache reporting structure we are currently using is illustrated in figure 2.

Figure 2. Cache Reporting Strucutre Currently In Use



The data we report daily is a combination of RMF device activity data from all the MVS CPUs and data from the RMF Cache Reporter for one system only. The reason for using cache data from only one system is that the cache controllers are shared among all the MVS CPUs, and, since they are unable to separate the data they maintain by CPU, report their total statistics to each machine's RMF files. The IBM recommendation is to report management data from shared cache controllers to only one CPU. [2] At our site, data was reported to all the CPUs as a convenience; however, using cache data from all the CPUs would cause all the cache counts to be reported multiple times.

The use of both data sources enables us to produce reports of cache performance and overhead which include response times and I/O rates for both cached and non-cached volumes. Statistics for two full strings are shown on each page. We have found these reports to be extremely valuable for tuning because they provide complete cache management data, including response time and statistics for non-cached volumes, in a convenient summary form. Examples of our reports are shown in figures 3 and 4.

The following measurements and derivations are of particular interest: 1. SIO Rate; 2. Average Response Time; 3. Control Unit Data Transfer Rates; and 4. Control Unit Utilization invisible to RMF.

The SIO rate is the total number of I/Os reported for the period, divided by the period's duration in seconds, giving the number of I/Os per second for the reporting period. The source for the reported number of I/Os varies according to whether or not the volume was cached, and whether it was accessed by a processor running MVS/XA or MVS/370. In all instances, we report cache data if it is available. If it is not, we must make due with RMF data for comparison, even though it is not exactly equivalent to the cache data. If the volume was cached over the reporting period, the value reported is calculated from counts maintained by the controller. It is the sum of search read cache requests (RF7SRCR), write cache requests (RF7WCR), read sequential requests (RF7RSR), and write sequential requests (RF7WSR). If the volume is not cached for the reporting period, the total number of SIOs reported is the sum of the SSCs to that volume from the MVS/XA processors, and the SIOs from the MVS/370 processors.

Average response time is the average time it takes to complete an I/O operation, from the initial issue of the SIO or SSC command to the hardware interrupt indicating successful completion of the request. Average response time is calculated every interval for each processor's I/O activity to each volume. In order to combine this figure meaningfully across all four systems, we weight the recomputed average by the number of SIOs from each processor.

The information necessary to derive the cache data transfer rate is available only from the model 23 cached controller. According to [1], " ... the 3880-23 counts the number of bytes transferred on its various data paths. The bulk of the control unit utilization stems from data transfer operations, and is more related to the number of bytes transferred than to the number of I/O Requests executed. Hence the division of these counts can aid in approximating what portion of the control unit utilization is contributed by each of the following four types of operations:"

The four operations referred to are: cache to channel transfer, DASD to channel transfer, DASD to channel and cache transfer, and DASD to cache transfer. The bytes transferred from cache to channel are transferred without DASD access; they satisfy read hit requests. Those transferred from DASD to the channel satisfy I/O requests that specifically bypass the cache. The bytes transferred from DASD to cache and channel are the part of a read miss that satisfies the request for a record, and updates the contents of the cache at the same time. (Note that cache controllers prior to the 3880-23 did not transfer to cache and channel simultaneously. They first transferred the requested record across the channel, and then initiated a staging transfer to update the cache [5].) The bytes transferred from DASD to cache are bytes transferred in staging operations. They are the part of a read miss operation that causes caching overhead.

We also use the count of bytes transferred in staging operations to derive two measures of cache control unit utilization. The first measure is connect time, or the amount of time the controller is actually busy with staging transfers. The second is the percent utilization added by the caching functions.

Connect time in this case refers only to connect time incurred as a result of caching overhead, which is invisible to RMF on the host machine. It is calculated by dividing the total number of bytes transferred in staging operations by an approximation of the transfer rate per second. As discussed above, bytes transferred in staging operations are transferred from DASD to the cache (field RF7DCCDT in the SMF user record). The transfer rate for a 3880

model 23 is generally listed at 3MB per second; however, if we were to divide the bytes transferred by 3MB, we would arrive at the amount of connect time spent actually transferring data, with no allowance for the overhead associated with the channel protocol, etc. In order to derive a more realistic figure, we divide the bytes transferred by 2.5MB, which provides an allowance for connect time not devoted exclusively to data transfer.

The percent of time the controller was occupied with cache overhead functions is then determined by dividing the derived connect time (in seconds) by the duration of the reporting period (in seconds). Note that the percent utilization figure accounts only for control unit utilization attributable to caching overhead, and not for utilization reported to RMF. Under MVS/XA, it is possible to determine the control unit utilization reported to RMF by dividing the reported connect time by the reporting interval. The sum of control unit utilization for all processors accessing the string, plus that contributed by the caching overhead, would be equal to the total controller utilization for the configuration.

4. Using the Reports for Tuning.

According to Friedman [3], "If performance (of the cache) is not optimal, I/O response time will be no better than the baseline uncached subsystem, and in extreme cases, it can be significantly worse." Therefore, the first step in tuning the cache with the Cached DASD Statistics report, figure 3, is to look at the response times. If the average response time for the string and each of its volumes is acceptable, there is no need to look further.

If, however, cached I/O response time is not faster than uncached, one should examine the reports further. At this point the control unit data transfer rates should be examined. If a disproportionate amount of data is being staged (bytes transferred form DASD to Cache), the problem may lie in excessive controller utilization.

As mentioned earlier (section 2), the greatest performance liability of caching is the controller activity generated by staging. If the overhead report (figure 4) shows a high percentage of cache overhead controller utilization, the controller may be saturated. In this case, decreasing controller activity may substantially improve response times for the volumes on the string.

In order to decrease controller activity and improve response time, poor cache candidates should either be removed from the string, or excluded from the cache. The current school of thought is that removing a poor candidate from the string is a better solution than excluding it from the cache [3,4].

Poor cache candidates can be identified by a low read hit percentage, and a high overhead contribution. If however, all the volumes contributing to cache overhead are showing good read hit percentages and high SIO rates, poor response time may be caused by nothing more than too much activity. In this case, performance may be improved by replacing some of the most frequently accessed volumes with ones that are less in demand [3].

5. Conclusion

Most widely available cache performance reports seem to rely on only the data provided by the cached controllers, forcing the performance analyst to depend on a variety of sources for complete information when tuning a cached I/O subsystem. This paper has described a method whereby the cache data provided by the IBM Cache RMF Reporter may be combined with RMF response time and device activity data to provide a consolidated report which is far more convenient for the analyst to use. First, it discussed the background of the problem, then, some of the measurements which can be used in cache tuning, and the methodology for producing the reports. Finally, it provided a thumbnail sketch of how the reports may be used for tuning a subsystem.

BALANCED EXPONENTIAL APPROXIMATION ALGORITHM

Arun Kumar and Melur K. Raghuraman

Prime Computer Inc.,
500, Old Connecticut Path,
Framingham 01701

ABSTRACT

A new non-iterative approximate formula called The Exponential Approximation is presented to estimate statistical performance of single class, fixed rate, closed product form queueing networks. This approximation is combined with Balance Job Bounds to develop a new non-iterative algorithm called The Balance Exponential Approximate Algorithm. This algorithm is more accurate than both the Balance Job Bounds and the Exponential Approximation. This algorithm has the accuracy and the speed to be attractive for applications requiring little computation and fair accuracy.

1. Introduction

Closed Product Form Queuing Networks are widely used in models of computer systems. A number of approximate solution techniques exist for solving such networks [1, 2]. Most of the approximate solution techniques are based on iterative algorithms that are often expensive in terms of computation and storage requirements. For many practical applications, a very high degree of accuracy is not required. Often analysts require a "back-of-the-envelop" type of a technique to answer various bottleneck related questions. The iterative algorithms may be "over-powered" for such applications. Clearly, a simple and an easy to use technique for solving queueing networks is needed. This paper describes one such technique for single class, fixed rate queueing networks.

The Balance Job Bounds (BJB), as described by Zahorjan [2], meets some of the criteria outlined above. As the name implies, Balance Job Bounds give bounds on performance. These bounds can be used as estimates of performance. They are very accurate when the system is balanced, i.e., when the service demand at all centers is equal. Unfortunately, their accuracy is not acceptable when they are used to estimate performance of systems that are not balanced.

We describe an approximate technique called the Exponential Approximation, whose results are fairly accurate for unbalanced system. Then we show a method of combining the BJBs and the Exponential Approximation such that the combined solution is more accurate than the two parent techniques.

2. Balance Job Bounds (BJB)

The Balanced Job Bounds estimate the upper and the lower bound of throughput and response time for single class, fixed rate queueing networks.[1]

[1]In this paper, the term 'queueing network' refers to a single class, fixed rate queueing network.

Consider a network of k queues. Let D_l be the service requirement at center l, D_{max} be the largest service requirement among all centers, D_t be the sum of all D_ls and D_{avg} be the average service requirement. If there are n jobs in the queueing network then the Upper Balance Job Bound (UBJB) and the Lower Balance Job Bound (LBJB) for throughput are specified by equation (1) and (2) respectively.

$$UBJB(n) = Minimum(1/D_{max}, \ n \ / \ [D_t + (n-1)D_{avg}]) \quad (1)$$

$$LBJB(n) = n \ / \ [D_t + (n-1)D_{max}] \quad (2)$$

The UBJB is close to the exact solution for nearly balanced systems. The LBJB, on the other hand, is accurate when the load is equally concentrated at k1 (k1 <= k) centers with little service requirement at the remaining (k-k1) centers. The Balance Job Bounds have poor accuracy for unbalanced systems.

2.1. Examples

We illustrate BJB using the following two examples. We shall use these examples again later in the paper. The first example considers a queueing network that is nearly balanced. The second one considers a queueing network that is not balanced. Both systems have one CPU, three disks and eight batch jobs. It is required to estimate the throughput of these system.

Queueing Network A

Center	CPU	Disk1	Disk2	Disk3
ServiceDemand	0.24	0.27	0.23	0.26

Queueing Network B

Center	CPU	Disk1	Disk2	Disk3
ServiceDemand	0.4	0.1	0.2	0.3

Solution Queueing Network A

```
The throughput using the exact MVA technique [3]
was computed to be 2.893.

EXACT(8) = 2.893
```

Let us obtain the throughput estimated by the Balanced Job Bounds.

$D_{max} = 0.27$

$D_{min} = 0.23$

$D_t = 0.24 + 0.27 + 0.23 + 0.26 = 1.0$

$D_{avg} = 1.0/4 = 0.25$

$n = 8$

Substituting these values in equations 1 and 2, we have,

UBJB(8) = 2.909 error = 0.556%

LBJB(8) = 2.768 error = 4.315%

Solution Queueing Network B

The throughput using exact MVA technique [3] was computed to be 2.384

EXACT(8) = 2.384

Let us obtain the throughput estimated by the balanced job bounds.

$D_{max} = 0.4$

$D_{min} = 0.1$

$D_t = 0.40 + 0.10 + 0.20 + 0.30 = 1.00$

$D_{avg} = 1.0/4 = 0.25$

$n = 8$

Substituting these values in equations 1 and 2, we have,

UBJB(8) = 2.500 error = 4.889%

LBJB(8) = 2.105 error = -11.673%

These examples illustrate, as has been earlier stated, that balanced job bounds are accurate for balanced systems, but they may not be sufficiently accurate for unbalanced systems.

3. Exponential Approximation (EXAP)

The Exponential Approximation technique is based on two simple observations. The throughput of a queueing network is zero when the number of jobs in the network is zero. It asymptotically approaches $1 / D_{max}$ as the number of jobs in the network increase. We use an exponential equation (3) to fit this description of the throughput curve.

$$T(n) = EXAP(n) = a[1 - \exp(-b*n)] \quad (3)$$

where a and b are constants, and n denotes the number of jobs in the network.

The throughput when there is 1 job is $1 / D_t$ and the throughput when there are infinite jobs is $1 / D_{max}$. These values can be used to determine the constants a and b.

Solving for a and b and substituting the result back in equation (3) we obtain:

$$EXAP(n) = (1 / D_{max}) [1 - (1 - D_{max}/D_t)^n] \quad (4)$$

Equation (4) is the exponential approximation for the throughput. The response time R(n), when there are n jobs in the network, can be obtained using equation (4) and the Little's Law.

$$R(n) = n / T(n) \quad (5)$$

3.1. Examples

We obtain throughput for Queueing Networks A & B using the exponential approximation.

Queueing Network A :

EXAP(8) = 3.405 error = 17.698 %

Queueing Network B :

EXAP(8) = 2.458 error = 3.126 %

The results for queueing networks A and B are summarized in Table 1.

TABLE 1
Percent Error Table

	LBJB	UBJB	EXAP
Queueing Network A :	4.315%	0.556%	17.698%
Queueing Network B :	-11.673%	4.889%	3.126%

Table 1 illustrates an important relationship between the accuracy of the Balanced Job Bounds and the accuracy of the Exponential Approximation. We observe that when the Balance Job Bounds are accurate, the Exponential Approximation tends not to be accurate and vice-versa.

The following argument explains why the above property holds. It has been shown [2] that as the number of jobs in a queueing network approach infinity, the throughput of the network asymptotically approaches the inverse of the maximum service demand. That is, the center where the service demand is maximum has the greatest affect on the throughput of the queueing network.

The Balanced Job Bounds, by their very definition, are accurate when the service demand is same at all centers. However, as the network becomes unbalanced, the throughput of the queueing network tends to be largely influenced by the center with the maximum service demand. Both the Balanced Job Bounds reflect this fact and their estimates become accurate as the number of jobs in the queueing network approaches infinity (or is very large). However, their accuracy is often not very good when there are moderate number of jobs in the system.

The equation (4) for exponential approximation is based only on the maximum service demand and the total service demand. When the system is balanced, there is no single dominating center. Therefore for balanced systems, exponential approximation is not very accurate. For unbalanced systems, where there is a dominating center, the exponential approximation tends to be quite accurate. We have observed this fact empirically but are unable to derive mathematical bounds on the accuracy of exponential approximation.

Thus it seems that the two techniques complement one another. This indicates that better accuracy may be obtained if somehow the two techniques could be combined.

4. Balance Exponential Approximation Technique (BEAT)

In this section we describe a technique that combines the Balanced Job Bounds with the Exponential Approximation.

Consider the following estimates of throughput for a fixed rate queueing network:

Formula1(n) = EXAP(n)
Formula2(n) = UBJB(n)
Formula3(n) = LBJB(n)
Formula4(n) = (UBJB(n) + LBJB(n))/2

Our goal is to develop a test procedure for a given queueing network, such that the output of this test procedure indicates one of the above four formulas to be used to estimate the throughput of that queueing network.

We observe that the exact throughput of a queueing network can be expressed in a closed form for a small number of jobs. In particular, the exact throughput of a queueing network when there are only two jobs in the queueing network is specified below:

$$EXACT(2) = 2Dt / (D_t^2 + \sum D_k^2) \quad (6)$$

In order to obtain the throughput of a queueing network with **n** jobs, first the throughput for that network with only two jobs is computed using each of the approximate formulas and using equation (6). The formula that estimates throughput with least error when there are only two jobs in the network is used to estimate throughput for that network when there are **n** jobs in that network.

4.1. Examples

We compute the throughput of queueing network A and B using BEAT.

Queueing Network A

First compute the throughput using each of the four formulas and using equation (6) when there are only two jobs in the network.

Formula	Throughput	Error
EXACT(2)	1.599	0.000
Formula1(2)	1.730	0.131
Formula2(2)	1.600	0.001
Formula3(2)	1.575	-0.024
Formula4(2)	1.587	-0.011

Formula2 (that is UBJB) has least error when there are only two jobs in the network. Therefore the Upper Balance Job Bound is used to compute the throughput when there are eight jobs in the network. This has already been computed in section 2.1 to be 2.909. The exact throughput when there are eight jobs is 2.893. Thus the error using BEAT is 0.556%.

Queueing Network B

The throughput when there are only two jobs in the network is computed using the four formulas.

Formula	Throughput	Error
EXACT(2)	1.539	0.000
Formula1(2)	1.600	0.062
Formula2(2)	1.600	0.062
Formula3(2)	1.429	-0.110
Formula4(2)	1.514	0.024

Formula4 gives least error when there are only two jobs in the network. Therefore formula4 is used to estimate throughput when there are eight jobs in the network.

UBJB(8) = 2.500
LBJB(8) = 2.105
Formula4(8) = (2.500 + 2.105)/2 = 2.303

The exact throughput when there are eight jobs in the network is 2.383. Thus the throughput estimated using BEAT has an error of 3.3%.

5. Accuracy and Validation

BEAT has been tested on a large number of queueing networks. The results are summarized in Table 2 and in Figure 1. The following test methodology was used. The number of jobs in the queueing network were varied from 5 to 20. For each job value, one

hundred random networks were generated. The number of centers in the network were randomly chosen from 2 to 50. For each random network generated, one hundred random samples of loading were generated. The service demand at each center varied randomly from 0.0 to 1.0 .

Figure 1 shows that BEAT is significantly more accurate than the Balanced Job Bounds and the Exponential Approximation. Although the maximum error for BEAT was observed to be 15.6 %, normally the results are more accurate. About 90% of the times, the error in throughput was observed to be less than 5%.

Table 3 indicates the frequency of selection of the four formulas in the tests conducted. It is interesting to note that about seventy percent of the times the average of the Balance Job Bounds is used. The Lower Balance Job Bound is very infrequently selected.

An additional point of interest in Figure 1 is that the Upper Balance Job Bound seems to be more accurate than the Lower Balance Job Bound. This appears to contradict Zahorjan's [4] observation that, in general, Lower Balance Job Bound is closer to the exact solution than the Upper Balance Job Bound. In our tests, we observed that the average error for Upper Balance Job Bound is less than the average error for Lower Balance Job Bound, but the maximum error for Upper Balance Job Bound is higher than the maximum error for Lower Balance Job Bound.

6. Conclusions

In this paper, a new technique to solve single class fixed rate queueing networks was presented. The accuracy of this technique is sufficient for many practical applications. As this is a non-iterative technique, the computation and memory requirements are minimal. Therefore this technique promises to be attractive for applications requiring little computation, fast response, and fair accuracy.

SENSITIVITY ANALYSIS OF SYSTEM CHANGES UNDER A PRODUCTION ENVIRONMENT

T. L. LO
McDonnell Douglas
Aerospace Information Services Company

ABSTRACT

System changes such as migration and modification always require full functional compatibility between the old and new versions of the system. The performance impact of system changes, however, does not seem to receive the same attention as functional compatibility due mainly to its complex nature, especially under a production system environment in which workload varies. This paper discusses how to use a regression modeling approach to determine the level of acceptance of a system's changes under a production environment in which workload condition is not controlled. Several examples on MVS/XA, VTAM, and ISPF migrations are presented.

INTRODUCTION

When a change is introduced to a system software, hardware, application program, or workload profile, system performance is likely to be affected. A change can be, for example, a new release of an access method, such as IBM's Virtual Telecommunication Access Method (VTAM) or an operating system migration, such as IBM's Multiple Virtual Storage (MVS) system. Most DP installations evaluate the changes only from functional compatibility viewpoint in a standalone environment. As long as the same (or better) functions are provided, the evaluation is likely complete. When the changed system is put into production, there is a chance that performance can be noticeably altered by the changes which are tested for their functional compatibilities, but not for their performance impacts.

There are, however, installations that do both functional and performance testings on system changes. The most common approach is benchmarking, in which a set of jobs, representing a range of typical workloads, are executed with and without the changes in a standalone testing environment. Thus, the workload is controllable. Although the evaluation of changes is straightforward in that the difference in performance between the new and old versions can simply be reported, the success of this approach depends on how well the benchmark represents the real workload, and how one interprets the results. Examples of this type of approach are synthetic benchmarks and the teleprocessing network simulator (TPNS).

The synthetic benchmark approach (BUCH69) utilizes one program with adjustable input parameters, such as number of CPU loops and number of I/Os, etc. running as a batch job in an attempt to represent the characteristics of certain production workloads. It requires fewer resources and can be executed many times within a fairly short period of time. The TPNS approach is designed to simulate the performance of on-line applications, such as IMS and TSO, using a set of properly designed scripts to represent the unique characteristics of the application it simulates. It requires physical facilities such as computer systems, front-end processors, and disk storage, and also requires manual manipulation.

The other approach, which draws much less attention than benchmarking, is to evaluate the changes on the performance of a real workload under a production system. That is, the system is run with and without the changes under an uncontrolled workload environment after the functions of the changed system are verified. Evaluation of performance impact in an uncontrolled workload environment can be complicated since any change in the system may also be affected by a workload variation as well as the change itself. Therefore, it is necessary to determine to what extent the system performance impact is acceptable. Consequently, a number of performance indicators need to be identified in order to determine the degree of tolerance on performance impact.

Due to its complex nature, a statistical analysis approach seems to be an ideal tool for evaluating system changes. One technique is to use regression models which correlate variables describing performance indicators to variables describing the uncontrolled workload variation and system changes. This paper explores the applicability of regression models in determining the degree of tolerance on the performance impact possibly caused by system changes. The first section reviews the general regression models; the second section illustrates the application of these models on various production system and application changes with examples; the last section briefly discusses the pros and cons of this technique.

REGRESSION MODELS FOR SYSTEM CHANGE EVALUATION

A regression model used for evaluating system changes correlates two types of variables: workload variables that describe system changes and workload variations, and performance variables that describe performance indicators. Each of the workload and performance variables in a regression model can be specified at either the micro (detailed) or macro (composite) level. Since the micro level involves immense data collection, reduction, and analysis efforts, most regression models deal with only the composite level.

The general form of a regression model can be expressed as follows.

$$Y(j) = \sum_{i=0}^{N} A(i)X(i) \quad \text{for } j = 1,\ldots M$$

where X(i) is a workload variable that describes various workload and system conditions, A(i) is the unknown regression constant, Y(j) is the performance variable corresponding to the jth set of workload variables, N represents the number of workload variables, and M is the number of regression sets. The X(i)'s can be further grouped into two categories: one describes workload and the other describes the system environment. There are two basic steps when applying regression models: the first one considers system changes only and the second one considers both system changes and workload variations. Friedman and Waldbaum (FRIE75) pro-

vided a detailed description of regression The following discussions follow their general notations.

ANALYZE CHANGES WITHOUT WORKLOAD VARIATION

The first step in using a regression model is to temporarily ignore the workload variation and analyze the performance variables under various system conditions. For example, if the response time is chosen as a performance variable, then its cumulative distribution function under various system conditions can be examined using the averaged response time for the 50th, 90th, and 95th percentiles. If there is an observed difference between two system conditions, a least squares fitness model should be used to further explain the source of difference. The least squares estimate of the unknown regression constants, A(i), can be found by solving the normal equations expressed in a single matrix form:

$$X'XA = X'Y \quad \text{where } A = \begin{bmatrix} A(0) \\ \vdots \\ A(N) \end{bmatrix}$$

and X is a (M x N) matrix whose columns correspond to various system conditions, and X' is the transpose of X. A hypothetical example is used to illustrate the fitness model.

If there are three different system processing conditions represented by X(0), X(1) and X(2) variables with 35, 9 and 8 days of data collected, respectively, then

$$A = \begin{bmatrix} A(0) \\ A(1) \\ A(2) \end{bmatrix}$$

and X is a 35x3 matrix whose columns are X(0), X(1), and X(2) respectively. The fitness model matrix is then

$$\begin{bmatrix} 35 & 18 & 8 \\ 18 & 18 & 0 \\ 8 & 0 & 8 \end{bmatrix} \begin{bmatrix} A(0) \\ A(1) \\ A(2) \end{bmatrix} = \begin{bmatrix} \sum_{i=1}^{35} Y(i) \\ \sum_{i=1}^{18} Y(i) \\ \sum_{i=28}^{35} Y(i) \end{bmatrix}$$

Therefore, the following combinations of A(i)s indicate different system environments:

* A(0) + A(1) -- the first system condition
* A(0) -- the second system condition
* A(0) + A(2) -- the third system condition
* A(1) -- the difference between systems 1 and 2
* A(1) - A(2) -- the difference between systems 1 and 3
* A(2) -- the difference between systems 2 and 3

In order to test the statistical significance of the observed differences without considering workload variations, we need to make further assumptions that the unexplained variations are distributed uniformly, with zero mean and variance equal to a constant that can be estimated from the residue, which is the difference between observed and fitted values. Therefore, the student-t test can be used on the basis of the estimated standard error of a coefficient. A student-t is equal to the ratio of the coefficient to its standard error. If there is strong evidence indicating that a real difference exists between two system conditions, the result can substantiate the observation that two system conditions are statistically different.

ANALYSIS OF WORKLOAD WITH WORKLOAD VARIATIONS

The second step is to include workload variations in data analysis in order to determine whether the observed performance disparity can be accounted for by the workload variation. Furthermore, if there is a difference, can it be explained by both types of variables ? Thus, the regression model is required to adequately correlate both workload and system conditions to performance indicators.

The complexity of this approach lies in determining whether the observed differences of performance indicators are constant under any two system conditions and any workload. If so, we may be able to assume that the effect of the system condition is independent of the workload variation. This can be studied using parallel regression models.

On the other hand, if the parallelism does not exist; that is, the difference is not a constant under any two system conditions and any workload, then non-parallel regression models are required. Since non-parallel regression involves more complexity (i.e. more sophisticated regression equations and verifications on model adequacy, etc.), this paper only explores parallel regression models. While it should be noted, however, that even parallel regression model may not be entirely appropriate in certain cases, they still can provide some explanations on performance differences.

The general parallel regression model has the following form:

$$Y = A(0) + \sum_{i=1}^{N} A(i)X(i)$$

Based on the way the system conditions are arranged, the general equation can be arranged into a set of models, each corresponding to a specific system condition. Using previous hypothetical example, the general model can be represented by the following models:

System cond. 1: $Y(1) = A(0) + A(1) + A(3)X(3) + \ldots$.
System cond. 2: $Y(2) = A(0) + A(3)X(3) + \ldots$.
System cond. 3: $Y(3) = A(0) + A(2) + A(3)X(3) + \ldots$

Again, A(0) represents the effect of system condition #2, A(1) represents the difference between system conditions #1 and #2, and A(2) represents the difference between system conditions #2 and #3. Note that other coefficients (e.g. X(4),...X(N)) correspond exclusively to workload variables, and are the same for different conditions, based on the parallel regression assumption. Therefore, this set of models enables us to study the effect of performance difference due to system conditions separate from workload variation.

Assuming this model is correct, then several common statistical fitting techniques can be used. The student-t test can examine each coefficient for different system conditions. Note that the effect of workload variables is now considered, and if the effect can be accounted for by workload alone, the t-statistic corresponding to a specific coefficient would be insignificant.

The other fitness parameter that is worth considering is R-square, the multiple correlation coefficient which describes the proportion of variation accounted for by the fitted regression model. If the parallelism assumption is correct, the R-square value would indicate

the adequacy of the model if there is a real difference between any two conditions.

Another useful statistic for checking model adequacy is the residual sum of squares which attempts to provide an unbiased estimate of the unknown variance of the fitness errors. By plotting the residuals, the outlying observations, systematic departure from randomness, non-constancy of variance, and nonnormality can all be examined.

MODEL APPLICATION AND CASE STUDIES

CASE STUDY #1 - MVS/XA MIGRATION

When IBM's MVS/XA operating system was announced, several of its advertised performance improvements had already convinced many DP installations to take advantage of MVS/XA without knowing what the real impact it would have. The migration study here (KELL83) involved an IBM 3083 model J processor with 24 I/O channel and 24 MB of real memory. The operating system was MVS/SP to be replaced by MVS/XA.

Three sets of benchmark jobs were chosen to measure the performance difference. The first set consisted of batch jobs representing a wide range of production application programs such as Assembly, catalog, utility, SORT, DASD, VSAM and various language compilers. The second set consisted of a group of selected on-line application programs such as SAS, SPF, MARK IV, etc. The third set was the real time application such as IMS and CICS.

The system conditions were naturally MVS/SP and MVS/XA, represented by X(0) and X(1) respectively. System execution time (Y) was selected as The performance variable with 50th (Y(1)) and 95th (Y(2)) percentiles. The workload variables were CPU time (X(3)), I/O time (X(4)), and multiprogramming level (X(5)). For the real-time application, the number of transactions per hour, X(6), was added to the workload variables.

The prime shift hours (0800-1700) of weekdays were used to collect data on performance and workload variables with respect to different system conditions. Data of two weeks before and one week after the MVS/XA migration were collected. Although it did not seem sufficient to satisfy the statistical significance, that was all the time given without impacting the production environment. Data collected can be grouped into a matrix form such as the following based on workload and performance variables and system conditions:

X(1)	X(2)	X(3)	X(4)	X(5)	X(6)	Y(1)	Y(2)
0	1						
0	1						
0	1						
1	0						
1	0						
1	0						

where X(1) = 0 and X(2) = 1 represent the MVS/SP condition and X(1) = 1 and X(2) = 0 represent the MVS/XA condition.

The first step of changed system evaluation is to temporarily ignore workload variables. The following tables summarize the analyses. Table 1 shows the batch benchmark results. Y(1) and Y(2) represent 50th and 95th percentiles of the number of runs of an application respectively.

X(1)	X(2)	Y(1) HH.MM.SS	Y(2) HH.MM.SS	Application name	# of runs

Table 3 Real Time Benchmark Results

As highlighted in Table 1, there were observable differences in execution time of DASD, SMP, OEM and possibly PL/I application programs. It is necessary to test

their statistical significance in order to determine whether these differences are caused by workload variation. The general least squares fitted model is

$$Y = A(0)X(0) + A(1)X(1)$$

or in a single matrix form,

$$\begin{bmatrix} 15 & 5 \\ 5 & 0 \end{bmatrix} \begin{bmatrix} A(0) \\ A(1) \end{bmatrix} = \begin{bmatrix} \sum_{1}^{15} Y(i) \\ \sum_{10}^{15} Y(i) \end{bmatrix}$$

Therefore, A(0) represents MVS/XA condition and A(0) - A(1) represents MVS/SP condition. In order to test the statistical significance, we need to further assume that the unexplained differences are normally distributed, with zero mean and variance equal to a constant that can be estimated from residuals.

The t-statistics corresponding to the coefficient A(1) for the 50th and 95th percentiles are:

	DASD	SMP	OEM	PL/I
50%	-0.73	1.19	1.71	-0.09
95%	-0.91	1.77	3.04	-0.92

Since t > 2, there is strong evidence that there is a real difference between MVS/SP and MVS/XA on the OEM application whereas SMP programs only showed a marginal difference.

Although the t-test indicated that there was a real difference on the OEM application, we need to expand the analysis in order to include workload variables to determine whether the effect we observed could be attributed to workload variation. Thus, the parallel regression model is needed.

Recall that the parallel regression model assumes that, if the model is correct, the difference in performance under any two system conditions and any workload is independent of the workload. Since A(1) represents the difference between MVS/XA and MVS/SP, the t-statistic associated with A(1) can be used to examine the model's assumption. That is, if the difference can be accounted for by workload alone, the t-statistic corresponding to A(1) would be insignificant.

The parallel regression model consists of two equations corresponding to 50th and 95th percentiles of the execution time.

$$Y(1) = A(0) + A(3)X(3) + A(4)X(4) + A(5)X(5)$$
$$Y(2) = A(0) + A(1) + A(3)X(3) + A(4)X(4) + A(5)X(5)$$

where X(3) is OEM CPU time, X(4) is the number of I/Os, and X(5) is the multiprogramming level.

The original data of 74 OEM runs were used to yield t-statistics and R-square value for the 50th and 95th percentile response times between MVS/XA and MVS/SP conditions. Table 4 shows the summary of the coefficients, t-statistics, and R-square of the fitted model.

	Y(1)	Y(2)
A(0)	0.218	0.233
A(1)	0.449	0.988
t(A(1))	3.171	5.617
R-square	0.61	0.57

Table 4 OEM Statistics with Workload Variables

Since the t-statistic corresponding to A(1) indicates that the difference is significant and the R-square value does not show a strong correlation of variation accounted for by the fitted model, the workload variables alone are not responsible for the difference. Further investigation revealed that there were two incompatible local modifications which caused an adverse effect (longer execution time) under MVS/XA.

CASE STUDY #2 - VTAM MIGRATION

ACF/VTAM release 3 with Extended Network Addressing (ENA) capability was designed to provide relief for those subarea craving installations and we were one of them. As usual, all functions under release 3 were tested for their compatibility but none of the performance impact was assessed. After the implementation of ACF/VTAM release 3 on one of the TSO systems (an IBM 3084Q with 96 MB of real memory under MVS/XA operating system), slow sporadic TSO response times were reported.

A TSO script was developed in an attempt to determine whether the new release was responsible for the slow response time problem. The script was executed from a locally attached terminal, a remote terminal, and a local terminal on a system running under VTAM release 2. The script was run twice each day for five days at each terminal at 1000 and 1400 hours which are the peak resource demanding periods in our environment.

Therefore, three system conditions were to be studied. A local terminal under VTAM release 3, a remote terminal under release 3, and a local terminal under VTAM release 2. A VTAM I/O trace was activated during script execution and RMF monitor was also used to trace the activity of that particular terminal in an attempt to correlate response time reported by RMF and VTAM.

The performance variables were average response time, network time, inbound VTAM time, outbound VTAM time, host processing time, and 90th percentile on total response time. The workload variables were number of transactions as seen by RMF and VTAM, CPU utilization, number of TSO address spaces, and average TSO user working set size. It should be pointed out that the network time here included data transmission time, user think time and/or typing time. Hence, it is not a truly data transmission time. The data matrix corresponding to performance and workload variables are shown in Table 5.

	X(1) X(2) 1 0	X(1) X(2) 0 0	X(1) X(2) 0 1
X(3) RMF # TX	59	59	59
X(4) VTAM #TX	58	58	58
X(5) System CPU%	88.1	79.3	89.2
X(6) TSO CPU%	43.3	9.7	44.7
X(7) #TSO ASID	183	13	190
X(8) TSO WSS (KB)	441	313	438
Y(1) IN VTAM (ms)	1.021	1.19	1.196
Y(2) OUT VTAM (ms)	0.923	0.49	0.931
Y(3) HOST time (sec)	0.912	0.851	1.195
Y(4) RMF resp time	0.927	0.807	0.975
Y(5) VTAM resp time	0.932	0.857	1.206
Y(6) RMF 90% R.T.	2.466	1.660	2.375
Y(7) VTAM 90% R.T.	2.59	1.751	2.453
Y(8) Network time	6.65	7.55	7.19

Table 5 TSO Script Timing & Resource Usage Statistics

Where X(1) = 1 and X(2) = 0 represent the system condition that local terminal user executing script under VTAM release 3; X(1) = 0 and X(2) = 1 represent the system condition that remote user executing script under VTAM release 3; X(1) = 0 and X(2) = 0 represent the system condition that local terminal executing the same script under a system running VTAM release 2.

As indicated in Table 5, the outbound VTAM time between The two releases was obviously different. Both average and 90th percentile response times reported by RMF and VTAM on the two releases were also different. A t-test statistic confirmed that there was a significant difference on outbound VTAM time between the two releases ($t > 4$), but no significant difference on local and remote terminals running under release 3 ($t < 0.5$). Further investigation revealed that system condition #2 (X(1) = 0 and X(2) = 0) was not a TSO system and the delays due to paging, swapping and device queuing were much smaller than the other two system conditions. Therefore, the response time difference between the two releases was attributed to workload variation.

The outbound VTAM time was investigated further since the difference was significant. It was discovered that the default value for the pacing parameter was different in the two releases. When the load is less intensive, the queuing time between host and outbound VTAM interface is insignificant. As the load increases, so does queuing time, although not proportionally.

CASE STUDY #3 - TSO & ISPF MIGRATION

The Interactive System Productivity Facility (ISPF) operates under Time Sharing Option (TSO) to allow users to develop, test, and execute programs interactively. It is a manually driven facility to assist users with many programming tasks in developing applications. The TSO system is an IBM 3084Q with 96 MB of real memory under THE MVS/XA operating system. The average number of logged on TSO users was 270 including 20 CAD/CAM users. The other workload included a small test CICS system and a small IMS test system. Batch jobs ran as a background application.

In order to utilize the virtual storage constraint relief offered by MVS/XA, and additional functions under the new release of ISPF, a decision was made to replace TSO/E 1.0 with TSO/E 2.1 and ISPF 1.1.0 with ISPF 2.1.2. A set of TSO scripts were developed to study the performance impact.

Script #	Description
1A	TSO/E basic functions (no ISPF)
2A	ISPF/PDF script for ISPF 1.1.0 no TSO/MON ISPF sysevents
2B	ISPF/PDF script for ISPF 2.1.2 no TSO/MON ISPF sysevents
2C	ISPF/PDF script for ISPF 2.1.2 include TSO/MON sysevents concatenated ISPF/PDF libraries
2D	ISPF/PDF script for ISPF 2.1.2 combined ISPF/PDF libraries No TSO/MON sysevents
2E	ISPF/PDF script for ISPF 2.1.2 like 2D with added ISPCTL0 in log-on procedure; recovery turned off.

The performance variables were:

* TSO trivial transaction response time
* TSO all transaction response time

The workload variables were:

* CPU %
* Paging (demand, swap and total)
* TSO transaction rate
* TSO TCB CPU time per transaction
* TSO total memory
* TSO average memory per resident user
* CAD/CAM average memory per resident user

There were five different changes associated with the study:

* (001) - TSO/E 1.0 & ISPF 1.1.0
* (010) - TSO/E 2.1 & ISPF 2.1.2
* (011) - TSO/E 2.1 & ISPF 2.1.2 with adding two swap data sets, removing one paging data set, adjusting SRM parameters, removing TSOMON ISPF interface
* (100) - Similar to #3 with modified log-on procedure to pre-allocate working data sets
* (101) - Similar to #4 with two PTF modifications, and increased system think time.

The detailed comparisons can be seen in (OBER86). The following tables only present the summarized results. Table 6 shows the summary of comparisons on five system conditions with respect to performance and workload variables.

System condition	X(1) =	0	0	0	1	1
	X(2) =	0	1	1	0	0
	X(3) =	1	0	1	0	1
CPU util. %		84.4	89.6	84.6	83.7	84.2
Demand paging		52.0	107.0	43.0	38.0	40.0
Swap paging		63.0	111.0	243.0	233.0	172.0
Total paging		130.0	231.0	296.0	280.0	220.0
TSO TX rate		13.9	14.0	13.1	12.9	13.0
Triv. TX resp.		0.39	0.43	0.40	0.36	0.36
Total TX resp.		0.93	1.26	1.17	1.03	1.02
TSO TCB CPU/TX(ms)		57.0	73.0	71.0	75.0	73.0
TSO EXCP/TX		12.36	13.61	14.20	13.96	13.01
total memory(MB)		37.32	42.33	31.36	30.05	33.97
TSO avg WSS (KB)		328.0	360.0	453.0	440.0	441.0
CAD/CAM WSS (KB)		824.0	754.0	925.0	934.0	937.0

Table 6 TSO/E & ISPF Migration Data Comparison

Since the paging activities, TCB CPU/TX, and average WSS were significantly different between the two TSO/E and ISPF releases, further analyses were conducted to determine if the difference could be explained. Table 7 shows further CPU, memory and I/O comparison on the two different releases with respect to various scripts described above.

	TCB+SRB Sec.		TCB Sec.		EXCPs		Memory	
TSOE	1.0	2.1	1.0	2.1	1.0	2.1	1.0	2.1
1A (TSOE)	1.89	1.98	1.77	1.88	269	270	196	220
2A/2B (ISPF)	2.46	3.75	2.21	3.47	355	476	251	315
2A/2C (ISPF)	2.46	3.74	2.21	3.46	355	476	251	327
2A/2D (ISPF)	2.46	3.62	2.21	3.35	355	446	251	326
2A/2E (ISPF)	2.46	3.45	2.21	3.18	355	427	251	326

Table 7 CPU, Memory & EXCP Comparison on TSO/E & ISPF

Table 8 shows the PDF function comparison between 2A and 2B (ISPF 1.1.0 vs 2.1.2) and 2A and 2E (ISPF 1.1.0 vs 2.1.2 with a modified logon PROC, no TSO/MON and no recovery).

Function	TCB+SRB Sec. 1.0	2.1	2.1	TCB Seconds 1.0	2.1	2.1	EXCPs 1.0	2.1	2.1
Browse	0.184	0.277	0.285	0.144	0.237	0.235	33	32	31
Edit	0.530	0.842	0.720	0.462	0.763	0.650	94	128	114
3.1	0.128	0.178	0.175	0.108	0.160	0.160	19	21	21
3.2	0.344	0.432	0.430	0.312	0.398	0.395	40	45	45
3.8	0.584	1.22	1.22	0.520	1.140	1.140	54	119	116

Table 8 PDF Function Comparisons for TSO/E and ISPF

Since the scripts were executed only once in each condition, the normal t-statistic could not be applied, nor any other regression models. Therefore, the only way was to manually observe the difference in response time.

The response times between TSO/E 1.0 & ISPF 1.1.0 and TSO/E 2.1 & ISPF 2.1.2 releases were different (35% in total and 10% in trivial transactions). As tuning changes were introduced to the new release, the difference tends to become insignificant (< 10% in both types of transactions). However, the differences in workload variables were quite obvious (e.g. demand paging was doubled).

According to the vendor, the difference between the two TSO/E and ISPF releases was a trade-off consideration. The performance expectations from the new release of TSO/E and ISPF were:

* CPU time reduction
  - CLIST processing
  - Removal of local modifications
  - Library allocation
* CPU time increase
  - More libraries
  - TSO/MON interface
  - Authorized facility
  - ISPF 3.8 CLIST code execution
* Memory & I/O
  - Virtual storage constraint relief
  - Smaller working set size
  - more real memory for link pack area (LPA)
  - More I/O from ISPF 3.4
  - Less I/O to SYS1.BRODCAST
  - Smaller below-the-line private requirement for ISPF users

We observed following effects due to the new release of TSO/E and ISPF:

* Virtual storage - 584KB virtual storage constraint relief, 1364 KB increase in extended link pack area, and the net link pack area increase was 780 KB.
* Real storage - Link pack area increase of 464 KB, private area decrease of 2833 KB.
* Other areas - 28% increase in TSO TCB CPU per transaction; 10% increase in EXCPs per transaction; 76% increase in swap paging; 10% increase in average user working set size; and poor batch turnaround.

Again, the trade-off was to gain more functionality improvements and user friendly conversions while still being able to meet the service goal requirements.

CONCLUDING REMARKS

We have shown that traditional regression models can be used to study performance impacts due to systems changes under a production system environment where workload varies. We feel that this approach can provide useful information for an analyst to determine what is an acceptable level of tolerance between two or more different system conditions and what to do next after identifying the area of discrepancy.

The use of a regression model to study the performance impact due to system changes is a straightforward process. However, to interpret the results requires an understanding of basic statistical principles. In some case, the application of regression models is not as straightforward as it seems since there may not have sufficient data points to satisfy the validity of statistical analysis. Furthermore, the parallelism assumption may not be valid in certain cases even though it can provide useful information. When the real difference is not obviously observable, an automated tool would be desirable to eliminate some guess work errors.

Characterizing UNIX® Stream Mechanism Via Pipe Experiments

T. Paul Lee
AT&T Bell Laboratories
Crawfords Corner Road
Holmdel, NJ 07733

ABSTRACT

A stream is a full-duplex connection between a user's process and a device or pseudo-device in the UNIX® system. It consists of several linearly connected processing modules, and is analogous to a UNIX shell pipeline, except that data flows in both directions. It is anticipated that new drivers and protocols will be implemented using the stream mechanism. This paper presents a simple characterization of this mechanism by experiments using stream-based pipes (SPIPEs). Factors varied in the course of the experiments were read/write system call message sizes, pass-through procedure call versus service scheduling, null service versus CRC-16 generation/verification service, and the number of modules pushed on the stream device.

We have found that, stream-based pipe has slightly higher throughput relative to a similarly configured pipe with message sizes up to 256 bytes, the default internal message size. Throughput beyond this point is hampered by the need to break up large messages. By setting a stream option to overwrite the default internal fragmentation for large messages, stream-based pipe throughput is also higher than that of regular pipe for very large message sizes.

To determine stream performance in a more realistic environment, a simple CRC-16 stream protocol was implemented. When simple table-driven CRC-16 generation/verification processing is performed on a per-message basis for each stream module, the throughput of the stream pipe is determined by CRC-16 calculation overhead for larger message sizes. This implies that with realistic message processing, the throughput of any stream device will be predominantly determined by the message processing overhead; the overhead induced by the basic stream mechanism is negligible.

1. *INTRODUCTION*

A stream is a full-duplex connection between a user's process and a device or pseudo-device in the UNIX®* system [1]. It consists of several linearly connected processing modules, and is analogous to a UNIX shell pipeline, except that data flows in both directions. Data flows are regulated by high and low watermarks associated with each module. Each stream processing module consists of a pair of queues, one for each direction. A queue comprises not only a data queue proper, but also two routines and some status information. One routine is the *put procedure*, which is called by its neighbor to place messages on its data queue. The other, the *service procedure*, is scheduled to execute whenever there is work for it to do. The objects passed between queues are pointers to blocks obtained from a memory allocator. Although each queue module behaves like a separate process, it is not a real process to the UNIX operating system. Queue processing routines do not block when they cannot proceed, but must explicitly return control.

This stream mechanism is an an important new feature of UNIX System V Release 3.0 [2,3]. New drivers and protocols will be using the stream mechanism in their implementations. It is important to have some quantitative insight and understanding on the usage of the stream mechanism. It is difficult, however, to characterize the stream mechanism by itself without the context of a driver or protocol implementation. We have thus adopted the pipe measurement strategy (referred to as PIPE) used in [4], using throughput as the primary performance index. The PIPE experiments measure the throughput between two communicating processes that take turns to do reads and writes through two shared UNIX pipes. Throughput is measured in bytes per second as a function of the number of bytes in each read/write system call. We call this benchmark program SPIPE, i.e., stream-based PIPE.

We investigate the throughput of the SPIPE benchmark by varying the following factors :

a. message size for each read/write system call.

* UNIX is a registered trademark of AT&T.

b. pass-through put procedure call versus service scheduling.

c. number of modules pushed onto the stream device.

d. null service module versus CRC-16 generation/verification service module.

2. OVERVIEW OF THE EXPERIMENT

The SPIPE benchmark creates one or more stream-based pipes (SPIPEs); each consists of a pair of duplex connections between two processes as depicted in Figure 1. In order to enable measurements on a stand-alone machine, a loopback pseudo-device at the bottom of the stream device is used to "connect" these two processes. Two loopback drivers are used for each pair of processes in one SPIPE instance. One process in the SPIPE connection writes a given number of bytes to one stream device and waits to read from the other stream device. At the same time, the other process attempts to read the given number of bytes from the first device, and then writes that number of bytes to the second device. Two processes are thus synchronized to do read and write in turns. There is a "forced" context switch after each write for both processes.

Since the methodology of the SPIPE and PIPE benchmarks are similar, we compare the throughput between these two measurements. The SPIPE uses no intermediate modules in the loopback driver and messages are passed down (and up) directly when the high watermark of each module is not exceeded†. The number of bytes transferred between these two processes divided by the elapsed time (in seconds) is the throughput of the SPIPE.

All measurements were conducted on a AT&T microcomputer†† for various message sizes : 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, and 4096 bytes. Measurements with only one SPIPE instance are reported here. Results with more than one SPIPE instance operating concurrently do not provide more insight in the context of the experiment.

The stream mechanism permits message processing and passing to be done in two ways depending on the urgency of the task to be carried out. Using pass-through procedure call facilitates the processing and speeds up the message flow from one module to another. In contrast, invoking service scheduling alleviates the contention for important resources such as CPU, but the system overhead in doing such scheduling can be significant. As part of our characterization, we compare the throughput between the pass-through put procedure call and the stream service scheduling strategy. We pushed one and two modules, a null put procedure and a null service procedure, on the stream device for these experiments. These null procedures only provide the necessary stubs to get their minimal functionality with no other processing involved. To ensure that the high/low watermarks do not affect the measurements, we used a high watermark of 10000 and low watermark of 1 for these experiments.

We also experimented with somewhat realistic modules that get pushed on the stream devices. These stream modules generate and append a CRC-16 (Cyclic Redundancy Check) checksum [5] for each message transmitted to the bottom level pseudo device driver. For messages received, the modules verify the correctness of the CRC-16 checksum and strip off the checksum bytes before passing the message back up. The CRC-16 checksum generation and verification processing is table-driven. For each byte received, two (one for each 4-bit nibble) look-ups were done in a 16 by 16 table. Using these modules, we have been able to gain some insight on the extra overhead of a modest amount of message processing relative to that of the basic stream mechanism. Checksum generation and verification is usually an integral part of any driver or protocol implementation that involves sending and receiving messages.

3. ANALYSIS OF THE RESULTS

3.1 SPIPE versus PIPE

Figure 2 depicts the throughput results for SPIPE, SPIPEB, and PIPE as a function of message size. SPIPEB refers to an SPIPE with QBIGB (BIG Queue Buffer) flag set to overwrite the default internal fragmentation for large messages. When QBIGB is set, the write buffer will not be fragmented at the default 256-byte boundary and a larger size (power of 2 up to 4096-byte) buffer can be used. However, unused buffer space with QBIGB set may become a problem in terms of efficient usage of shared buffers managed by the stream mechanism.

With message size of 1 byte, we can compute that it takes **4.90** msec of CPU time to pass down and back up one byte through the stream mechanism. This number derives from the inverse of the throughput result, and includes a *read*, a *write*, and a full *context switch* overhead. Figure 3 shows the percentage difference using the PIPE throughputs as the reference base line data. The SPIPE has 5% higher throughput for message size of 1 byte, and the gap narrows percentage-wise as message size increases. SPIPE throughput becomes worse when message size is greater than 256 bytes. This situation is reversed by

† The high and low watermarks, 10000 and 1, used in the experiment are different from those supplied with the original modules, i.e., 512 and 256.

†† This performance study was based on an early prototype of the Stream implementation; some changes and enhancements were made to the prototype since.

setting the QBIGB flag in the immediate module downstream as shown clearly in Figure 3. Large message size in SPIPEB provides the advantage of single data copy operation as compared to PIPE which copies data 1K bytes a time. Although setting QBIGB has significant impact on this benchmark, it should not be regarded as a universal rule in using the stream mechanism in general.

3.2 Pass-through versus Service Scheduling

Next we investigate the throughput differences between the pass-through put procedure call and service scheduling strategies for every message passed between modules. In order to ensure that exactly one service is scheduled for each message passing through, a high watermark of 10000 and a low watermark of 1 are used. Figure 4 depicts the percentage degradation in throughput relative to the zero-module pass-through SPIPE. It shows that service scheduling causes drops in throughputs of 22% and 33% relative to the pass-through put procedure call with one and two intermediate modules pushed on the stream, respectively.

3.3 CRC-16 Service versus Null Service

A null module was modified to perform table-driven CRC-16 processing on a per message basis for messages going downstream as well as upstream. Figure 5 shows the throughput for one and two CRC-16 modules with service scheduling. It is interesting to observe that throughput for the SPIPE benchmark starts to level off when message size is larger than 512 bytes. This implies that the per-byte overhead of the CRC-16 processing for each message becomes the dominating factor of the SPIPE throughput; thus, the relative overhead of the basic stream mechanism is small. For comparison, Figure 6 depicts the throughputs for the similarly configured SPIPE with null service and CRC-16 services for each message processed.

It is of interest to compute the per byte cost by inverting the throughput results. We can then verify the relative overheads between a null service module and a CRC-16 service module. The per byte cost (CPU time in microseconds) for message size of 1024 bytes for the null service module and CRC-16 module are listed below :

	one module	two modules
null service	23	30
CRC-16 service	106	193

For the one module case, the CRC-16 processing per module (2 queues) is about 83 microseconds per byte, and which is more than three times larger than the 23 microseconds per byte required for null service.

4. CONCLUSIONS

We have presented a simple characterization of the basic stream mechanism by using the SPIPE (stream-based PIPE) benchmark. The SPIPE throughput results are slightly better than those of the PIPE results when the message size is small. Relative throughput becomes worse as message size increases beyond 256 bytes. This is due to the internal message fragmentation in the stream mechanism. When SPIPE has the QBIGB set, it significantly outperforms PIPE with message size greater than 1024 bytes. When very little processing is done on the data, overall performance is heavily dependent on buffer sizes.

We have further quantified in the context of the SPIPE benchmark the throughput difference between direct pass-through put procedure call and service scheduling provided by the stream mechanism. The difference is significant enough to justify careful examination of more efficient implementation of service scheduling in the stream mechanism. It also indicates that we should be judicious in using service scheduling strategies in actual driver or protocol implementations.

Finally, the experiments with CRC-16 modules have shown that the overhead of the basic stream mechanism is relatively small for realistic implementations of protocols and drivers.

ABSTRACT

A model for analyzing the extent of fragmentation in a UNIX* System V file system is described in this paper. The extent of fragmentation is measured in terms of the reductions in disk access time if the file system is reorganized. Since reorganizing a file system is a time consuming operation, such a measure provides an incentive to reorganize the file system if noticeable performance improvement is expected to result. In this paper we describe the model, its implementation and some experimental results in controlled and real environments.

The original motivation for this model is an expert system for UNIX System tuning. The paper briefly describes this tuning tool and how the model is utilized by this tool to provide more specific information to the user.

1. INTRODUCTION

In this paper we describe a model for analyzing the extent of fragmentation in the physical layout of files on a UNIX System V file system. The amount of fragmentation is measured by the reductions in the disk i/o time if the file system were optimally organized. The fragmentation results from frequent addition and deletion of file blocks in a multi-user environment, and it can introduce excessive disk head movements in sequential file access. This methodology has been implemented and the implemented module provides information regarding the organization of file systems to TUNEX[1], an expert system for UNIX tuning[1] Here, we present the model, its implementation and a number of experimental results. This model is based on the UNIX System V file systems and its input are derived from the System V measurement utilities. Thus, all references to UNIX system refer to System V version.

The System V file system construction command (*mkfs*(1M)[2]) [2] uses two parameters, *gap* and *blocks/cylinder*, to arrange the list of free blocks in an order that typically results in more efficient access time. The parameter *gap* is the number of physical blocks between every pair of consecutive blocks on the free block list, and *blocks/cylinder* is the number of blocks on a cylinder. With proper selection of *gap*, it is expected that initially the consecutive file blocks are within some optimal rotational distance on the same cylinder if possible. The idea is to reduce the disk seek and latency times by placing the files in a logically contiguous space.

The operating system does not make any attempts to maintain this organization however. As file blocks are added and removed, they become more scattered over the file system space. Hence the file system's layout starts to deteriorate that results in excessive seek and latency times. This is particularly significant since the positioning of the disk head over the requested block is in general the most time consuming of the i/o process.

The age of a file system can also reduce the access efficiency of its directory blocks. Directory blocks hold an entry for every file in the directory. As files are deleted, the corresponding entries in the directory blocks are nulled out. Although these null entries may eventually be reused, their existence in excessive numbers, can cause long directory searches and i/o overhead.

A UNIX system utility (*dcopy*(1M)) reorganizes the file system by placing consecutive blocks of a file within an optimal rotational gap, on the same cylinder if possible. It also places the more recently accessed files closer together. In addition, it compacts the directory blocks to remove the null entries, thereby reducing directory sizes.

The reorganization is a time consuming operation and the file system must be unmounted, otherwise, its consistency cannot be ensured. Furthermore, there is

little indication of how unorganized the file system is and how much its reorganization would affect the performance. In very dynamic environments, an organized file system can become unorganized in a matter of days. So, the performance gains resulting from a reorganization may not last long enough to justify the efforts needed to perform this operation. For these reasons and because the improvements are difficult to quantify, system administrators either hesitate to reorganize file systems, in which case the disk i/o operations may become very inefficient, or they reorganize regularly, which may not be necessary.

Here, a model is described that evaluates the extent of randomness in the physical layout of files. The results can help us make a decision on whether a reorganization is necessary and worthwhile. The model includes a number of assumptions and approximations that may at first seem rather crude. Nevertheless, we are able to show that this simple model is sufficiently accurate to distinguish situations where the gain from reorganization will or will not be significant.

The paper is organized in 5 sections. In section 2 the details of the model are presented. This section also describes the approach in obtaining values for model parameters. Section 3 contains the experimental results. Section 4 describes the original motivation for the development of such a model which is an expert system for UNIX system tuning. Finally, in section 5 a summary of the paper is presented.

2. THE MODEL

The fragmentation measure, C, is defined as the average reduction in disk access time per block access, if the file system is reorganized. This is equal to the unnecessary disk head movements resulting from the fragmented layout. This movement is called *unnecessary* because it is not required when the file system is organized. Thus,

$$C = S+L$$

where S and L are the average unnecessary seek and latency times per block access.

The random positioning of file blocks on the disk drive affects i/o performance most when consecutive file blocks are accessed consecutively. This type of access will be called *sequential file access*. Many commands and applications require sequential access to data and executable files. In the case of sequential file access, the unnecessary seek and latency times correspond to the seek and latency times between accesses to consecutive blocks of files. We make the assumption that:

(A1) The application programs access files sequentially.

This assumption can be relaxed by letting a percentage of file i/o activities to be of sequential nature and scale the performance measure appropriately.

In the presence of other disk i/o requests and depending on the disk scheduling policy, two consecutive i/o requests from the same application are not necessarily serviced consecutively. However, with a number of elevator type [3] and shortest seek time first disk scheduling policy, there is a high probability that consecutive i/o requests to the same or neighboring cylinders are served consecutively. On the other hand, if the requested blocks are far apart, the driver may schedule other requests between the two. In this case, if the file blocks are scattered, the disk head needs to make some unnecessary movements to read the next requested block in sequential file access. To compute the unnecessary disk head movements, we further make the assumptions that:
